CONTENTS.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. **The bigah** *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

CORRESPONDENCE.

COFFEE LEAF DISEASE.

TO THE EDITOR.

SIR,—In the issue of the *Indian Agriculturist* for December, I was much struck with an article under " Coffee Leaf Disease" as being of a nature better calculated to lead to a clearer and more enlightened view of the matter than obtains in the meantime. The manner in which you have treated the subject too, should make those people, who are so confident of sulphur and lime being the only remedy for leaf disease, weigh the matter more fully before giving vent to assertions which very frequently assume a dogmatic character.

With your permission, I would offer a remark or two on what in my humble opinion is the true secret of the subject, and which you ably put into these few words. " In looking into the sources of this disorder, we must go back to first principles". . . . and that " we interfere with the natural order of things, we want more seed and fruit than the bushes would produce in the ordinary course of Nature, and hence we adopt measures to that end." Everybody will I think agree as to the truth of these statements, but I suspect that the same unanimity will not exist in regard to the remedies suggested. If I understand you, you appear to advocate a system of non-intervention when the tree would seem to me to require it least—after it has given a large crop; for without coming to its relief by a judicious application of manure and the pruning knife, the results must prove disastrous to the tree in the first place, and secondly, to the revenue of the planter.

I consider that the solution of the problem is to be sought and found in quite another direction. In the wild state coffee has never been found growing except *under* the *shade* of *forest trees*, hence would it not be the most natural conclusion to arrive at, that it is in following Nature as closely as possible, the greatest success may be expected. By adopting the system of cultivating the coffee tree under shade, there are a great many other advantages besides the main one of not having its energies exhausted year after year with crops greater than it can well bear, which might be taken into account. The need for manure is less, owing to a copious deposit from the large trees which materially adds to the fertilization of the soil; the need for pruning is also lessened since the tree does not " make" the same amount of wood as when grown in the open, while the saving in the expenditure as regards weeding, digging, &c., is enormous. I am strongly of opinion, that if in Ceylon and elsewhere planters cultivate shade with the same assiduity as they pay to matters of minor importance, in less than ten years there would be very little occasion for so much talking and writing on the vexed question of Hemeleia vastatrix."

J. L.

CINCHONA IN HAPUTALE—SPLENDID RESULTS IN OUTTURN OF DRY BARK PER TREE.

(*To the Editor of the Ceylon Observer.*)

Broughton Estate, Haputale, [illegible]th Nov. 1879.

DEAR SIR,—Seeing an inquiry made in your paper a few days ago as to the average outturn of dry bark from cinchona officinalis trees of matured growth, and also a statement of yours that you thought 2lb. about the average, I beg to state that I have despatched 338lb. *dry* bark from 45 trees, that is 7·51lb. per tree. These trees were planted along the boundary of this estate about 10 years ago, where the soil is far from good, and were coppiced in July last, and the bark thoroughly dried in store before despatch.

The succirubra trees, coppiced at the same time, averaged 10·62lb. per tree: 1,094lb. from 103 trees, which though not so good an outturn as was obtained from some 400 trees felled on Sherwood Estate two

years ago, namely, 14·75lb. is by no means a bad average when it is remembered that the Sherwood trees were planted on good soil whilst these were simply put round the roads and patena boundary.

Yours faithfully,
H. H. CAPPER.

RASPING TEA.

SIR,—In the *Indian Agriculturist* of 1st October, I have been reading Article No. II., on "Drawbacks to the success of Tea," and as I have had a varied experience of four years in a London Brokers' office, ten years in mercantile life in various parts of India, and am at present in tea in Assam, I think myself in a more unprejudicial position than most people for judging some questions connected with the planters' interests.

The first objection I have to make to your article, is your statement that the Assam qualities, *viz.*, strength and pungency are solely in favour of the home China market, and a style of manufacture calculated to produce them you characterise as "simply ruinous."

My personal belief may be of little weight, but I am confident the average price of Assam tea could not be realised if it was bought for drinking, not blending purposes, and if the day ever comes when Assam has beaten China out of the London market, farewell to the Assam prices of the past, unless indeed it is still in demand for giving body to the hill teas. But the point I wish to make is, that, consumers cannot afford to compete with dealers for a special article used by the latter to raise the quality of a large bulk.

Wine merchants know how a small quantity of full flavoured and full bodied wine will improve the quality of a large quantity of inferior liquor, but the growers of the former know their interest lies in making a wine suitable for trade rather than consumption, as the public are quite unable to compete with the trade in such matters.

When Assam tea was at its highest, it was necessarily the most profitable for Assam planters. In those days a little Assam had to do a vast amount of work, and the competition for it, of course, was very brisk among dealers, but fancy consumers paying Rs. 5 per lb., and I remember one parcel fetching over Rs. 10.

As Assam deliveries increase, necessarily the value falls, and if eventually it supplants China, it will beat China prices, and then the question arises, can it be grown at those prices profitably? You look forward hopefully to that day as the millenium of the Indian tea planter, but personally I should bitterly regret it, but I have no fears of it ever coming to pass, as even at prices ruling in the early halves of 1878-79, many thousands of acres in Assam would go out of cultivation.

The second point I would controvert in your article, is the superiority of the London market for sellers over the Calcutta one.

You say you have closely studied the Calcutta prices as compared with the London ones, and find the latter higher. As in 1878-79, the market for the latter halves of those years has been a rising one, it would naturally be the case, but your conclusion that as people continue to ship tea, therefore it must pay, though it should be true, I regret that every one acquainted in the smallest degree with Indian trade, knows there is no "must" in the matter at all.

In my experience there is very rarely a margin of profit between Indian and home prices in all kinds of produce, and most shipments are made on the hope of the market rising between shipment and arrival, and so realising a profit. In proof of this you have the numerous recent failures on both sides of India, and if you know many, or say any merchants retiring with fortunes, though out here many years, you are more fortunate in your acquaintances than I am. Some firms have done well by systematic *bearing*, always selling forward at home, trusting to the market falling to enable them to cover here at a profit, but such firms are in a very small minority, and men with capital find the home markets more advantageous to work upon than the Indian as being lower in the long run.

In short I deprecate your advice to planters both as regards style of manufacture and market for sale, but I hope some day when Indian trade is in a sound condition with fair margins for the merchant to work upon, that it will be the interest of all of us planters to ship the bulk of our teas to London, but that day I am afraid is still far distant.

NONDESCRIPT.

BAMBOO FOR PAPER STOCK.

I.

SIR,—In his report on the Royal Botanical Garden, Calcutta, 1878-79, which appears in your journal for October, Dr. King remarks that his further experience gained during the year in the process of cropping clumps of bamboos has confirmed him in his opinion of the unsuitability of the plan proposed by Mr. Routledge.

I have shewn in previous letters and in a pamphlet I have published on the subject, that Dr. King from the very first, misapprehended what he is pleased to term "my plant," but having instituted experiments on this erroneous basis in the year 1875-76, has persistently carried them on year after year with the infructuous result he again records.

It is very much to be regretted that during this somewhat lengthy period while experimenting upon a system he declared would not answer, so able a botanist having all facilities at command, did not simultaneously carry on parallel trials or experiments on some other system, (either his own or one of those recommended by Dr. Brandis) which promised better prospects of success, this however does not appear to have occurred to Dr. King, and he now therefore leaves the question just as he found it.

Fortunately for progress I have been more ably assisted through other channels (*vide* my letter of 24th August in your October issue), by which Dr. King's *Question No.* 2 in his report is conclusively answered, shewing that immature shoots of wild bamboos "*can be collected from the native forests and conveyed to a Factory;*" as also that they can be floated long distances and delivered under a cost of five shillings per ton, both facts disputed by Dr. King.

I am glad to say that Dr. King's *Question No.* 1, is also in a fair train for settlement as Dr. Ribbentrop, the Conservator of Forests in British Burmah, has inaugurated plantations under irrigation, which will authoritatively test this important question, and has published his opinion that irrigation will he believes, materially promote the productive growth of bamboo, thus not only would be the cost of cutting and carrying so bulky an article as young bamboo shoots be materially reduced, but strict surveillance kept over their collection, a very important point in ensuring regularity of quality.

Although no doubt from the native forest, under proper supervision, the young season shoots can be cut and collected at a very low cost, the danger will always exist of some older growth being mixed with the young stems, which would be extremely prejudicial to the quality of the "stock" manufactured, selection or sorting after cutting being extremely difficult, indeed after the stems have been crushed and dried, it is almost impossible to detect and separate the old from the young; and I perhaps should explain that for economy of manufacture, and to ensure high quality of fibre, it is essential that the young shoots should be cut while the sap is flowing, and before they have attained full development or maturity, for this and foregoing reasons I give a most decided preference to plantations.

Dr. King's 3rd question remains to be considered, *viz*, "*A Floating Paper Stock Mill;*" I can only infer that Dr. King could never have seen a paper mill, or he never seriously would have made such a suggestion:—

Without entering into full details, the plant for a Paper Stock Factory would consist of 12 or more large iron vessels, each to contain 1 ton dry crushed bamboo, filled when working with say 1,200 gallons caustic alkali, to keep which boiling, steam generating boilers would of course be necessary as well as to drive the cutting, pressing, willowing, drying, and other machinery with baling presses. Obviously therefore heavy machinery of such a character is impracticable on any floating vessel, but were it otherwise as shewn in my last letter, bamboo will float, clearly therefore it would be far more simple and practical to float the bamboos to the factory, than the factory to the bamboos.

Should it be determined to collect the young season shoots from the native forest, a steam launch may be employed, the machinery arranged for driving crushing rolls, and the stems thus collected and crushed towed into lighters to a central factory.

It must, however, be borne in mind that under no circumstances are young shoots produced during all the year; a certain portion therefore as collected and crushed whether from plantations, or the native forest must be dried and stored for the continuous supply of the Paper Stock Factory, which like a paper mill must be worked night and day during the year, and such a factory to ensure commercial success, must be upon a scale capable of converting at least 100 tons bamboos (calculated as dry) into paper stock weekly producing say, from 60 to 70 tons merchantable stock.

Dr. King intimates in his report, "*that even accepting Mr. Routledge's estimate of its value,*" bamboo as a material for "the manufacture of paper can only be tested by practical paper makers," the inference is obvious, but although it may appear egotistical to say so much, I venture to assert that my judgment on this point will be admitted by our English Paper Trade, and I unhesitatingly state that no fibrous material that has come under my notice is so well adapted to meet paper making requirements as bamboo; the whole question so far as paper stock and paper therefrom having been conclusively tested, it only remains to organise the supply of bamboo in connection with Paper Stock Factories; the sale of the manufactured product being assured to almost an unlimited extent.

During the past few weeks in unison with the general rise of all articles of produce, the price of Esparto grass (the raw material on which at present the paper trade mainly depends) has risen from 30 to 40 shillings per ton, and the market is absolutely bare of stocks, we paper makers therefore are in rather a critical position. (Tripoli grass the cheapest quality, selling at £7 per ton.) I shall therefore be much surprised if with the revival of commercial enterprise, bamboo does not soon come to the front, as it is a material infinitely superior in quality to Esparto, and the pater stock therefrom producible at less cost.

THOS. ROUTLEDGE.

Claxheugh, Sunderland, 5th Nov., 1879.

II.

DEAR SIR,—On inquiring in the Reading Room of the Royal Colonial Institute, of which I am a fellow, I find your journal absent, which is regrettable, not merely in the interests of the institute where the papers of nearly all our colonies are filed and regularly transmitted, but being read there, would I doubt not, induce many subscribers judging from the interesting matter *I always* find therein.

The practice of the institute appears to be, to exchange compliments with Editors and proprietors of Colonial and other journals, they sending their papers and an annual book recording the meetings and events of the year.

They would I doubt not, pay the postage on your journal, if you thought well to exchange, but if you do not care for this, I doubt not by placing your journal before the Committee with a suggestion to that effect they would subscribe for it.

In any case I wish to see your journal in our rooms so kindly intimate to me or to Mr. Frederic Young, the Hon. Secretary, 15, Strand, London, what you will do.

I am going to put a case of bamboo in all its stages up to paper in the Museum, and if you have the back numbers in which you have so kindly inserted my several letters on Bamboo, by you, say from last January, I should be glad if you will forward them to the institute and let me know the cost, which I will hand your London Agent, who I assume will be Street and Company of Cornhill.

Our Esparto grass still continues to rise in value, Rags also have advanced in price from 30*s.* to 40*s.* per ton, therefore with the general commercial revival which now appears to be established, I trust ere long to see bamboo make a move.

THOS. ROUTLEDGE.

London, 19th November 1879.

THE ASHES OF MANURE.

SIR,—I see from your issue of Tuesday last, an extract from the *Pioneer* respecting Mr. Caird. In England he is considered a great authority, and in the extract I sent you he does not give a mere *on dit*, but the result of a careful experiment by the European manager, Mr. Robertson, at the Government Experimental Farm at Sydapet, near Madras, and he says he "ventured to press on Mr. Robertson the propriety of repeating the experiment." He also adds :—" Very great advantage to India is likely to result from the *well-considered* experiments carried out here by Mr. Robertson." You will find this article in *XIX Century* for September last. I have always been under the impression that as regards *fertilising properties, i.e.,* plant-food of a substance, the ash contained the whole or *nearly the whole* of the substance in itself or what it could absorb from the atmosphere or internally chemically reproduce. I give my authority from memory as I have not a copy to hand, *viz.,* Professor Johnstone's work on Agricultural Chemistry, the small edition. He either says the whole or nearly the whole ; or gives one or two exceptions. What I wish to point out is that Mr. Caird did not think the result improbable, but rather likely.

In a trip through South India many years ago, I was surprised to see how the land could give continual crops when the villagers burnt the whole of the dung of their cattle. Early in the morning numbers of women and children would be seen collecting the dung from the roads even, to be made into flat, round cakes stuck on the walls of their houses to dry, and afterwards to be used as fuel, but I did not known that it was carefully applied to their fields afterwards in the form of ashes.

[Our correspondent is quite right ; we had specially marked Mr. Caird's quotation from Mr. Robertson for notice ; the *Pioneer's*, paragraph did not refer to such statements of facts.—ED. *Ceylon Observer.*

IMMIGRATION INTO BRITISH GUIANA.

SIR,—In our memorial, dated 20th February 1879, we omitted to explain how it is that the infants and other children, in this colony, are shut out from the possibility of obtaining the free return passage to India, which it appears from Ord. 7, 1873, section 77, is within the reach of every such immigrant.

No infants above 5 years of age on arrival can by any means acquire a right to a free back passage, as they cannot under the existing law, as interpreted by the Immigration Agent-General obtain a Certificate of Exemption from labour. Ord. 7, 1873, section 77 provides that infants and minors may be indentured after their arrival, and while residing on a plantation, but this has never been carried out, and a resolution of the Court of Policy, dated Monday, 28th June 1875, has virtually abrogated section 77 by fixing the bounty on indenture on a plantation at a sum which no planter would pay, namely, $200. The bounty was raised in this manner avowedly to put a stop to indenture under-contracts under section 72, and it operates equally in preventing indenture under section 77.

If the Ord. 4, 1876, were carried out literally, no immigrant who had not been indentured on arrival, could get employment on a plantation. For Ord. 4, 1876, section 47 provides, that no person shall employ an Asiatic immigrant not under indenture until such immigrant shall have produced his Certificate of Exemption from labour, while the Immigration Agent-General holds, that no immigrant can be entitled to a Certificate of Exemption from labour, unless he shall have served five years under indenture, so that any immigrant born in the colony on arriving here under 10 years of age would not be eligible for employment. It is true the Immigration Agent gives them which he calls a Certificate of Freedom, but this is a document not provided for by law, and consequently null and of no legal value.

We beg to state that no reply or acknowledgment has yet been received from the Governor to our memorial.

ILAUDUM,

For self and others who signed the memorial.

British Guiana, 23rd October 1879.

MADRAS NOTES.

SIR,—It is a matter for regret that, owing to the financial crisis which the country has been brought to by amateur financiers, the efforts of the local Government are likely to be paralysed as far as regards efforts for agricultural improvement. That scheme so energetically propounded last year by Sir R. Temple in Bombay, also seems likely to collapse, if the reported refusal of the Secretary of State to appoint a trained officer to superintend the work to be carried out by the native instructors be true ; for without such an officer is it likely that the native teachers will be kept from gravitating back into the courses pursued by their ancestors, relations, and friends. Thus it seems that the abolition of the Etc. Department under the Government of India is to be accompanied by the extinction or nullification of all efforts for the improvement of native husbandry, notwithstanding the grandiloquent phrases made use of in the resolution abolishing the department named. Mr. Harman, who was, I believe, to have been appointed to superintend the work of agricultural education in Bombay, has recently returned from Australia, whither he was obliged to proceed on account of his health having broken down during his tours in Coorg, &c., when inquiring regarding the leaf disease. His health has, it is to be feared, been permanently injured in performing this duty, and his stay in India doubtful. His report regarding the disease is being looked for, but I suppose it is in the hands of the Mysore Government, and probably, as such documents usually fare, will not see the light until it is stale, and perhaps rendered useless by further discoveries.

It is confidently reported that some of the members, at least, of the Famine Commission have grasped the importance of the facts which show the agricultural condition of the country ; and Mr. Caird says that, what should be patent to all, we have an increasing population, but a stationary system of farming ; a state of things which of course cannot go on, for there must soon be found a limit to the increase of the arable area, which has heretofore met the increased demands for food to supply the wants of the growing population. There can be little doubt, I think, that our famines must be chiefly attributed, in their severe forms, to the backward state of our husbandry—an exhausting and impoverishing, instead of an improving and advancing one. And there are those who venture to assert that, had the country been under a higher system of cultivation in 1876, the Madras famine in all its horrors would never have occurred to devastate so many districts ; although of course they admit that with great failures of rain there must always be high prices.

• Mr. Caird I see endeavours to throw a doubt on the evil character of the practice of burning cattle dung; but he loses sight of two facts, which are of great importance in the question, and also certainly does not seem to have been aware of the results given in your October issue, detained at Bangalore. The facts I refer to are 1st, the loss of organic matter through burning, and thus of the consequent mechanical benefits to the soil, and, 2ndly, the fact that if wood were used as fuel, the ashes therefrom would go to swell the manure heap, *in addition to* the cattle dung. He also does not seem to remember the value of the urine of cattle, which is of course, when the solid excreta are used as fuel, totally wasted. The figures also on which he based his conclusions, show I think quite the reverse to what he states, if carefully examined. For, on looking them up, I find that it was only in the first cutting that the ashes gave the heavier return, whilst the second cutting of the fodder they had but little effect, bearing out the well-known fact that their action is very rapid. Mr. Caird would have done well to have weighed the results before him better, before jumping to a conclusion.

A correspondent of yours, I see, appears to try and deprecate the value of the education given in our local school of Agriculture at Saidapett; but surely he might have taken the trouble to understand what he was writing about before he ventured to give his opinion. He does not appear to be aware of the fact that model farming, as a means for improving agriculture has been given up in almost every country, and in Madras also, although the local Government did not long ago express themselves of the opinion that a model farm was a necessary adjunct to a good system of agricultural education, in this forgetting their previously express approval of the abolition of their own model farm, and also the experience gained in Germany, America, and England in connection with Agricultural Colleges. In this country in particular model farms are likely to be most particularly useless, as the native farmer is not at all prone to copy, nor is he one who is likely to perceive the advantages of improvements; add to this his ignorance, superstition, and conservatism, and the probable results from placing an example before him are not likely to be great, even if any at all are obtained at a cost at all commensurate with the improvement effected in his agricultural processes.

I quite believe that the founders of the institution referred to started with far too ambitious aims, and that the curriculum of study is much too scientific and not practical enough in its bearings. No more unfortunate place for teaching agriculture practically could have been chosen, for as regards its position, its soil, and surroundings, it is exceptional. There is no fair specimen of native agriculture near by; the district around being more than commonly in the hands of pauper cultivators. The students therefore have no chance of comparing, or of being shown the difference between the system recommended to them, and that pursued by the ryot according to time honored custom. But it must be admitted that agricultural education in any form, as long as it is sound, must be a benefit to the country, even though it may not be as effective and thorough as is desirable. That Hindu students will take to practical work, when they have sufficient inducements to do so, is shown by the fact that they will compete in ploughing matches such as the one held at Saidapet last year, and which is to be repeated very shortly. Last year the competition attracted a good deal of attention from the public, and the competitors were numerous.

AGRICOLA.

December 17, 1879.

KOTEGURH NOTES.

SIR,—The weather during the present month has been dry and bright. We have had only half-a-dozen days on which clouds appeared, and only one day which threatened rain, but nothing fell here all passed off to the snowy range, which soon had a new white covering.

The hill sides are now brown, and the deciduous trees have shed their leaves, and the country side is putting on its wintry appearance. The atmosphere continues generally clear, though at times it becomes slightly thick and hazy.

The following is a comparative table of the past five seasons :—

	1875.	1876.	1877.	1878.	1879.
Haily days	....	1	....	....	....
Wet	1	1	4	....	....
	Dry and bright.	Dry and bright.	Satisfactory.	Dry and bright.	Dry and bright.

Wind hardly any, when it comes it is from the N. or E. Frost commenced about the middle of the month, and during the last week water has frozen in the *gharrahs* in the bath-room.

The thermometer (Fahrenheit) hung in an open verandah (6,400 feet above sea level) W. aspect is about 45° in the morning, 54° in the afternoon, lowest 36°, highest 57°.

There is not much to record different from last month.

The birds are the same, though the vermin, rats especially, are in greater numbers than ever, and a good heavy frost, to thin their numbers will be duly appreciated.

The pink flowers of the wild sorrel (vern. *balora, malora*) came out about the 6th; the white waxy looking flowers of the wild oleander (nerium oleander) about a week later. Their advent is the sure sign of the beginning of winter. The leaf buds of the walnut and horse chestnut, and the fruit buds of the peach are forming.

The Rampur Fair was held on the 8th and 10th. Here congregate people from Tibet and from the plains of India for the purpose of exchange of commodities. In a late number of your journal you gave a short account of this fair, so I need not repeat. Rampore is the capital of the Native State of Bissahir, about 22 miles to the east of this place. The fair time is well attended and is looked forward to by the inhabitants, for many miles round, as a season of relaxation from the agricultural duties, and a means of laying in a stock of warm woollen cloths for the winter.

The villages are now busy threshing out the remainder of their autumn gathered crops, among which rice is the chief. They are also hard at work collecting firewood, pine-leaves for bedding for their cattle, grass, and leaves, and small twigs of trees for their goats and sheep. The men folk are now busy spinning wool, which they do in all spare moments, carrying a small basket (*kaondah*), containing cleaned wool (*ún*), on their left arm, and the spindle (*takkri*) with which they spin the wool, in their right hand; many twist the wool which they have spun as they walk along, and the operation is even carried on in the Naib Tahsildar's court when a case is in progress and by the different persons interested in it; women seldom spin, the labour being considered much too light for them. The women are told off to carry out and spread the manure in the fields, that being the proper kind of work for them, and they are now busy carrying out that operation, as the villagers consider it advisable to get the manure spread before the snow falls, so that its strengthening properties may be carried into the ground when the snow melts; at this season of the year there is but slight loss by evaporation consequent on the manure being now spread out over the fields. Chenopodium (*kala battú bitú*; similar to the English goosefoot and nearly allied to the quinoa cultivated in the Andes of South America, was harvested about the second week; it is not eaten alone but mixed with barley and the amaranth. Jowar ripens about the same time, it is cultivated in very small qualities, and by a few only of the better off zemindars. Hill potatos are being dug up and stored for winter use. The ploughing operations are nearly all over, only a very few fields—those lately under *kala battu* and hill potatos—remaining the barley was all sown by the first week, the first day of the Rampore, *viz.*, the 8th, being reckoned the last safe date. Some of the villagers now begin to press out apricot oil, the operation seldom takes place until the field work is nearly over and labour spared for the purpose. As I have already given full details in the Indian Agriculturist for July 1st, 1878, page 229, on the subject of the manufacture of apricot oil, I need say no more on the subject here. An oil mill, when the property of a *deota* (idol) is placed convenient for the use of the inhabitants of 3 or 4 villages; a small share of the outturn is given to the *pujaris* (priests) of the idol. Whoever arrives first at the mill and *lights a fire*, obtains the use of the mill for the day, and he can pass to and from his home or anywhere else, as often as he likes, and no one will interfere with the mill provided his fire continues to burn; if it goes out another person can at once make use of the mill.

In the garden we have zinia, mignonette, snap-dragon, narcissus, stock chrysanthemum, white china rose, red monthly rose, aster, scarlet geranium. In September phlox, partulacca, centaurea were sown, they came into flower, about the middle of the month, and still continue in blossom. Myrtle, fuschid, geranium, heliotrope, hydrangea, and other similar kinds of plants have been wrapped up in grass coverings since the middle of the month.

Peas sown in September are now ripe. There are still a few tomatoes, but they are almost tasteless. Also beet-root, carrots, cabbages, and jerusalem artichokes.

G. P. P.

Kotegurh, 30th November 1879.

The Indian Agriculturist.

CALCUTTA, JANUARY 1st, 1880.

THE GOVERNMENT AND THE RAYAT.

THE reforms so urgently wanted in the style of farming in this country, do not seem to be so emergent in their nature to the Government, as they do to private individuals, and there may be this excuse for that apparent blindness. The members of the Government look at most things from a purely fiscal point of view, while the outsider lives and moves among the rayats, knows all their little difficulties, and in many cases knows what would remedy them. The Government lives principally in the cerulean atmosphere of Simla, high out of the way of the cries of distress which float upwards from the villages. Their time is taken up with the mighty "affairs of State" while individual wrongs are unredressed because of this. The private resident of our Mofussil stations knows all the rayat's affairs, and is in a position to give the Government valuable information on all such subjects, but his position is frequently such, as not to entitle him to a hearing. We are not speaking now of the present Government, whose special manner of conducting affairs is a fair subject for politicians to discuss, but does not come within our province. Our remarks are general, and refer to the system of Government in this country. We have repeatedly drawn attention to this subject, and would once more point out the vast importance of the whole question of the rayat and his mode of farming. It is a truism that good Government means the "greatest good to the greatest number," and we must not forget that if we could confer any "good" on our agricultural population, we would thereby benefit the greatest number, as no less than 70 per cent. of our population depend directly on agriculture for their daily bread, and it may truly be said that the entire population depend on it indirectly. The very revenues of the country depend almost entirely on its success, and hence it comes, that a year of plentiful and seasonable rains means a year of sure revenue, while deficient or untimely rains mean a difficulty in realising the revenue of the district affected. It may thus be affirmed that there are few subjects of such absorbing importance to the Government of India as this, and it is a pity that they fail to see this, or seeing it, set about its consideration in so very perfunctory a manner.

We have lately been studying several departmental administration reports, and are astonished at the great diversity of produce in different districts, and these districts so closely situated sometimes, that it is hard to account for this difference on the grounds of diversity of soil or climatic influence. For instance, we find that in the district of Seoni in the Central Provinces, the produce of wheat per acre is only 120lb., while at Raipur, 150 miles distant, it is 454lb. Now it may be presumed that the soil and climate are not so very diversified as to account for this vast difference, and it may also be assumed that the cost to the rayats will be much the same in both cases, while the result to the two men is vastly different, to the one, it means an ability just to make both ends meet, while to the other, it means despair, financial ruin, and his getting deeper than ever into the toils of the bunia, and yet this does not seem at all an important subject to our Government. So very trifling indeed, is it considered, that when the recent scare in economy took possession of the gubernatorial mind, the Agricultural was the first department to go by the board. It is not exactly abolished, but is mixed up with a few other departments in such a way as to shew the value placed on it at head-quarters, and to speak ill for its consideration and the elaboration of details in its administration. Speaking of this produce per acre, reminds us that the average production of wheat per acre in the United Kingdom is about 1,600lb., while the average all over India is only 660lb., and how is this to be remedied, for it must be self-evident that a large annual outturn must be a vast benefit to the individual farmer, and ought to be equally so to the Government. One method for the improvement of farming, and one which has not been much noticed among the various schemes put forth by those who have the best interests of India at heart, is the system of raising the land revenue. As at present fixed, this charge is as unchangeable as a statute of the Medes and Persians of old, and "changeth not;" should the season be a good one, the farmer can meet it easily, as it is not a heavy charge *per se*, but a bad harvest places it beyond the rayat's power to pay it, hence a reference to the bunia, who advances the necessary amount, under an agreement whereby he receives the next crop at purely nominal prices. The general terms of the bargain being, that the rayat hands over his grain to the bunia in repayment of the advance with its concomitant interest, at so many seers per rupee beyond the rate ruling in the bazaar at the date of payment, the Tahsildar's *nirik* being the standard. This means a sacrifice of all his profit, which goes to the bunia, and compels the rayat to repeat the process in view of the succeeding crop. Now this would be obviated by the Government fixing a fluctuating percentage of the produce as the Government rent, instead of a fixed and unalterable sum in money. Say it was fixed at 12½ per cent., or two annas per rupee, not of the value of the crop, but of the actual crop itself, two great advantages would accrue. *First*, the rayat would not have to sell his grain in a falling market, or hand it over to the bunia to obtain the necessary cash to meet the putwaree's call, but would at all times be able to meet it in proportion as his crop turned out. If he had a good crop, he could afford to pay a heavy quantity of grain, and if his harvest were deficient, the Government demand would not complete his ruin, and *second*, the Government would on the average realize more profit from the soil by this method, and a more important end still would be attained. The amount of land revenue receivable being dependent on the amount of the crop harvested, would give the Government a direct interest in securing as many good harvests as possible, and the cause of improved agriculture could not fail to be benefited, by the interest which the revenue authorities would necessarily and naturally take in all that concerned the rayat and his affairs. Difficulties may be said to exist as to collection of revenue in this form, and as to its ultimate disposal, but those are details with which we are not concerned here, although we may note in passing, that we do not think them at all formidable with the existing staff of revenue officers, from the Chairman of the Board to the Tahsildar's chaprassie; we are convinced that ample material in the way of administration exists to enable the Government to cope successfully with all these objections. At all events these are for the consideration of our statesmen and lie without the province of an agricultural journal.

There are many other remedial measures which we might mention, but as we have already done so *ad nauseam*, we defer going over the same ground in the meantime. Some important alterations in the mode of assessment and distribution of canal water, will form the subject of future remarks. Meanwhile we take leave of the subject by drawing attention to its vast importance, both as concerns the rayat on the one hand, and the prosperity of our revenue on the other.

THE GENERAL TREATMENT OF FARM ANIMALS.

ONE of the great differences between plants and animals is, plants build up their tissues from inorganic compounds such as water, carbon dioxide, urea, and salines of various kinds, usually abundant in all fertile soils. Animals have not the power to do so, their food must be elaborated and prepared in the tissues of plants; and consists mainly of organic compounds. Plants absorb inorganic compounds directly from earth air, and water, and construct out of these, substances which may be generally classed so far as foods are concerned, into tissue formers or *proteids*, and heat producers or amyloids, starches, and fats. Animals eat plants, or other animals which feed on plants, and so make use of "these proteids and amyloids to build up their own structures. The tissues of animals in the various processes of life, and ultimately in death, are broken up into simpler substances which result in the production of carbon droxide, water, urea, and salines of the various sorts found in Nature.

The bodies of animals are in some respects like machines. No organ of the body can be in healthy action without producing force, and this force is produced at the expense of materials existing in the body, which undergo certain chemical changes that generally may be spoken of as combustion or oxidation. In a machine, the mechanical force is due to the heat force, generated by the burning fuel. There is this resemblance, but there is also a difference. The body of animals is self-repairing, a machine must be repaired by some agent outside of itself. During life the oxygen of the blood is sweeping everywhere over every particle of the body, and continually entering into combination with substances such as carbon and hydrogen. This union produces combustion, in the process of which heat and force are evolved. In the living body, oxygen is the servant, the scavenger, sweeping out all effete and hurtful matter. In the dead body oxygen is the lord and master, breaking up into innumerable compounds that very structure which in life it served to keep in health and action. Wherever the blood flows, it carries with it oxygen derived from the lungs, this implies oxidation of waste tissue and the production of waste matter. Every motion of the muscles, every throb of the heart, every breath drawn, every exercise of nerve force produces waste material, which must be removed from the body through the lungs, skins, kidneys, or other excretory organs if the animal is to be kept in health. The ultimate products of this waste have been already briefly noticed. They are taken up by the blood and carried to the excretory organs and expelled from the system.

In the selection, breading and rearing of farm animals, sufficient importance has not hitherto generally been attached to the physiological and hygienic principles which ought to govern and regulate operations so intricate and to the agriculturist so important. Certain peculiarities in the structure, constitution, and habit of these animals have been seized on, and these peculiarities further developed, until a point is attained, beyond which it may not be safe to go, lest degeneracy set in. The causes that originally produced the various breeds of sheep and cattle, found all over the world, up at least till the very recent period when the latest breeds took their rise under the conscious action and interference of man, are due mainly to "Natural selection and evolution," laws first brought into prominent notice and powerfully illustrated by Charles Darwin, the greatest naturalist that has appeared since the time of Couvier if not greater than he.

In the most famous breeds of sheep and cattle, famous that is for their coming to maturity in a very short time, noted for the speed in which they can be turned into beef and mutton, we venture to think that these excellencies have been attained at the cost of vital stamina. Instead of having to wander over a more or less extensive area in search of food, and to content themselves with but indifferent shelter from the rigors of climate, sheep and cattle of approved breeds have much, if not all of their food laid down to them, and but a fractional part they gather for themselves over a comparatively limited area. The less movement, the less waste of tissue, rest and quiet with abundance of proper food, and warm comfortable housing hasten the period of maturity and greatest weight. This tending of animals of approved breeds, thus concentrating all the functions and forces of their bodies in the direction of eating and resting, and eating again, must as a natural consequence tend to dwarf some organs of their bodies and render them liable to disease. It seems to us that the pleura-nemonia so very prevalent in Britain and elsewhere, has, as one main cause of its continual recurrence, the deteriorated con stitution, the deficiency of stamina, and the dwarfed and weak lungs of improved breeds. Of course wherever disease of this nature presents itself, it is communicable to other individuals on the same farm who may be subject to the same conditions which tend to produce deterioration in vital stamina. We remember a Veterinary Surgeon of some eminence in the North of England giving it as his experience, derived from the *post mortem* examination of numerous subjects, that there was scarcely an animal when brought to the knife of the butcher, that did not show a tendency to lung disease sometimes pretty well developed. This is a matter which we think could very safely have been predicted; and hence there is more than ever a pressing necessity that the sanitation and ventilation, especially the latter, of all buildings in use for cattle or sheep should receive a much greater share of attention and judicious contrivance to secure the health of the animals, than it has hitherto been the custom to bestow.

Just as in the case of the soil, agriculturist do away with the indigenous plants of Nature's own sowing, and in their stead plant and rear crops of their own, so with the animals breed on farms for their milk, butter, pork, beef,and mutton. Farmers interfere with their feeding and breeding, deprive them of much of their power to feed and breed at will, provide many things for them which in a state of Nature they sought and obtained in a greater or less degree for themselves, seized on those qualities and peculiarities which rendered them more valuable for farm purposes, and endeavoured to reproduce and further develope these, until a breed, distinguished for one or more points of excellence was attained. These improvements in all breeds of animals raised on the farm, even though effected in accordance with the laws of animal life, nevertheless have not been produced without a considerable loss of vital energy, a great falling off in the *hardiness* of the animals and a lower type of stamina, all of which imply a considerable loss in the power of all improved breeds to resist disease, once the conditions of disease have been developed, and a greater likelihood of their being more easily effected by everything that in any way tends to lower the normal type of health, and produce disease. We have said that in our opinion nc insignificant cause of the prevalance of "*pleura*" is due to th causes above enumerated. The "*rot*" and "*staggers*" in shee are really diseased livers produced by the stunting of tha organ in the general treatment of improved breeds. Th "*rinderpest* and. the *foot and mouth* disease that produce such widespread havoc, fifteen or more years ago in Britai and elsewhere in Europe, the measles and other diseases swine were neither "scourges of God" nor "inscrutab dispensations of Providence" any more than the plague, t black death, cholera, typhoid, and typhus fevers were. A these diseases are simply the result of the brut

ignorance of man, of those very laws which, whether men know them or not, cannot be violated with impunity. The rinderpest, like most gigantic evils was not without its uses. It was probably the only thing that would have stirred up agriculturists as a class, to greater precautions in the avoiding of diseases and to more rational treatment of their cattle; and probably the result of *pleura* in the long run will be, that if men will stunt the lungs of cattle in order that they may consume less heat-producing food materials, and hence take on fat sooner, they will find it their interest to be as careful of those weak dwarfed abnormal lungs as they can; it will pay in the long run, hence as we have said the whole subject of sanitation, and the general physiological and hygienic principles, that stand in such intimate relation to the health and breeding of stock of all kinds, must engage the attention of agriculturists a great deal more than it has hitherto done.

AGRICULTURE IN BURMAH.

(*Communicated.*)

THE state of agriculture in Burmah, the condition of the cultivator, what can be done to advance and improve these, are subjects which we intend to review in this paper.

British Burmah may be divided into two agricultural zones. If, during the dry weather we ascend any one of the great water-courses within 60 or 80 miles from its mouth, the eye meets nothing on either banks, but an interminable expanse of alluvial plain, intersected here and there by mangrove or tidal jungle, and perhaps a patch of rising ground looking like an oasis in the desert. These plains form the first zone. They are devoted to paddy cultivation, and nothing else will thrive on them. During the S.-W. monsoon, their retentive clay keeps the water which feeds the paddy crop, and when the cold weather sets in, as the water evaporates, they settle into a hard brick-like subtance, which no amount of labour or high cultivation will cause to yield profitable crop. These lands, year after year, yield the cultivator 60 to 80 and 100 fold, and he is well contented to let them rest a while and wait until a bountiful Providence will send him a natural fertilizer in the shape of plentiful rain. The high prices his produce commands, induce time to cultivate his lands as his forefathers did, he is entirely dependent on the rainfall, and knows that nothing will improve his crop if water fails him; if this is abundant, he increases his area, and in the end he finds his profit with a little more labour. A notion has long existed abroad that the Burmese cultivator is careless and lazy; those who believe this, have never been across paddy fields between June and August, let them do so, and they will gather different ideas. Nature and circumstances are kind to him, and it is not to be expected that without a stimulus he will go out of the old groove.

These plains then fulfil their mission, they will always yield the staple produce and be the wealth of the country; their cultivation increases yearly, and nothing but communications are wanted to see this increase reach its climax.

Beyond these plains lies the second zone, here the country and vegetation assume a different aspect. The mangrove and tidal jungles merge into savannahs and tropical forests. The grey muddy river bank is changed into a sandy loam covered with gardens and banana plantations, villages are ensconsed amidst a luxuriant, evergreen vegetation; the landscape is intersected with hills, and in the valleys which spread at their foot, the stiff plastic clay is vainly sought for. Here the paddy cultivator finds but a scanty harvest, the rainfall is lighter, and the sandy soil quickly absorbs the heaviest showers. In the dry season too the cold is more intense and the dew more abundant. In this part of the country immense forest tracts in which the decaying vegetation of centuries has formed a crust of rich humus soil, await the enterprising agricultural pioneer, and nothing has as yet been done or tried to bring to light the wealth hidden in these almost deserted tracts. Burmah with its virgin lands of unequalled fertility is still nothing but a paddy-producing country, and is still dependent on its neighbours for its yearly supplies of wheat, tobacco, oil seeds, and pulses,—dry or cold weather cultivation on high land is unknown here, it is confined to river banks, and no attempt has as yet been made by the cultivator to extend it to the inland parts, for what reasons we shall see further.

As we divide the country into two agricultural zones, so do we find two classes of cultivators. The first is the well-to-do paddy cultivator of the plains, he whose produce is the staple of export, he generally owns several yokes of cattle, he works only during the paddy season, he has no urgent need of money, and holds his crop until the greedy boatman gives him almost any price he asks for; he then lays in a stock of fish, buys a little gold for his wife and daughters, adds a few improvements to his house, and spends the balance of his earnings in dances and good works in the shape of resting-houses or monasteries, and awaits the coming monsoon. This man wants nothing, no improved agriculture will add to his wealth or to the wealth of the country, and any one going through his fields about October, will find very little to criticise if rain has been timely and copious; he knows that paddy requires a clean soil, he cleans it, Nature does the rest.

The other class of cultivators is that which dwells within the inner zone; here we find great scope for improvements. The cultivator is not poor, for he is not in debt, but in that portion of the country which would strike a stranger as being the wealthiest, we see the cultivator struggling for existence and hardly able to make both ends meet—and how does he succeed?

During the rains he cultivates a paddy field, but the nature of he land and the uncertainty of the rainfall brings him but a poor crop, if he gets a 15 or 20 fold return, he thinks his labour well-repaid. He lays in his store for the year and exchanges his surplus (when he has any) for fish. Another resource is now opened to him; the river bank and chur with their rich loamy deposits offer the prospect of an abundant harvest, on these after cutting and burning the grass and lightly scraping the surface, he plants tobacco which none but himself will con sume, and maize, cucumbers, and other vegetables which scarcely suffice to supply the demand in the neighbouring market.

Another means which is only resorted to by the poorest hillmen, Shans and Karens especially, is the loungyah cultivation.

During the hot weather a patch is cleared and burnt in the forest, when the rains set in, holes are dug about, and paddy, cucumber, pumpkin, sessamum, and sometimes cotton seeds are placed in holes, thus a miscellaneous crop is secured, the luxuriance of which shows at least the incomparable fertility of the soil.

The cultivator in these parts also generally owns a garden planted with mangoes, jacks, plantains, and other fruits, the produce of which adds a small contribution towards his welfare.

But he often gets tired of a life of unceasing toil, and the uncertainty of his returns makes him look with envy towards the plains below, then one day he migrates, and thus is the upper part of the country gradually becoming depopulated, until the plains have absorbed four-fifths of the agricultural population.

We have seen that the state of agriculture is all that can be desired for the present within what has been described as the first zone. At least the results are highly satisfactory, and whether the time for high cultivation, irrigation, and improved implements has arrived, may remain an open question; one thing is certain, as long as the cultivator will find eager speculators to give him prices which all expenses told, leave him over cent. per cent. profit, as long as his land-tax is only nominal, no effort will induce to him employ expensive implements or alter a system at once so simple and so profitable.

But setting aside paddy cultivation, we find every other branch of agriculture greatly backwards; we see a fertile part of the country in a stagnant condition, a population bearing the burdens of civilization without enjoying its advantages. It is a strange anomaly that one portion of the country with no natural disadvantages, should be returning to a primeval condition whilst the other is making rapid strides towards wealth; a paucity of population does not account for this fact. The best reason which can be given, is the neglect of agriculture, caused by the ignorance of the agricultural population.

They have not yet been made to realize that new wants have sprung around them, and that the supply of these wants would be a source of richness to them. They still live in the times when no more was required than to get enough paddy for food, and a little more to spare for the few requisites which could not be manufactured at home.

That Burmah can be self-supporting as far as food and oil grains are concerned, that it ought to export yearly enormous quantities of tobacco is well-demonstrated by the few unpersevering experiments which have been made, and that it is entirely dependent for these produce on the neighbouring countries, can also be easily ascertained by the imports of grains and tobacco. That a sheep is a curiosity, and that not a single bullock is bred in the country, are facts which any one who has travelled twenty miles from Rangoon, has had an opportunity to ascertain.

The measures adopted to improve this alarming state of things, have as yet been few. And it must be acknowledged that Government to whom it belongs to initiate the reform, has many difficulties to contend against. Agricultural Shows have been opened, but these have a very poor chance of effecting any good, so long as the people do not know what is required of them. In fact they only tend to mislead. A man grows 50 square yards of tobacco, he selects the finest leaves, brings them to the show, and gets a prize of say Rs. 30, of course he goes home with the belief that he has done very well. In the meanwhile the neighbouring market has to import thousands of maunds to meet the demand.

Before this man can be induced to grow wheat, tobacco, &c., on an extensive scale, he will have to be taught the high marketable value of these articles of produce and the large demand for them, it will also be necessary to show him how they are grown. In fact, before we have agricultural shows, we should have an *agriculture*, before we produce to exhibit, we should produce to supply our wants. In all countries exhibitions have followed, but not preceded the creation of industries, thus the way has been lead towards improvements and perfection.

An experimental farm was started about two-half years ago in the Arakan hill tracts; after many vicissitudes, working at great disadvantages of climate and labour, and having to struggle against the most untoward and unexpected difficulties, it is at last showing some signs of life and success. High land, at a distance from the river bank has been cleared, and promising crops are now growing; very favourable reports have been received on the tobacco cured at the farm, from which cigars second to Havanahs only, have been rolled. Sessamum has been raised during the rains, on land generally devoted to paddy. Thus a new agricultural era has been opened in Burmah, and so far, the experimental farm may be said to have been successful.

But the question has arisen whether in the face of many difficulties, especially the unhealthiness of the climate and the scarcity of labour, it is expedient to continue experimental farming at Myouktoung. The money expended and the difficulties overcome would be of little avail indeed, were the enterprise to be abandoned, it would again open speculations about the agricultural prospects of Burmah, such as have arisen after the several careless and unpersevering attempts which have been made. But the fact that difficulties have been overcome, mark the place as the most suitable for experimental farming. A successful crop at Myouktoung is the best criterion which can be desired, for that which is disseminated all over the country in the way of drawbacks, is found concentrated here, whilst the advantages the place may possess are to be met with in any part of Burmah.

The system of working however requires alteration, and lessons taught by past failures should be put to profitable use. If the object was merely to show that high land can be cultivated during the cold season with several crops, then the farm has fulfilled its mission. But if it is desired to ascertain whether land can be placed through a regular course of uninterrupted and remunerative cultivation, whether the capitalist or cultivator will find farming a practicable and profitable calling in Burmah, then it is necessary to abandon the primitive mode of cultivation pursued on the farm, which is only suited to sand banks. A novelty is being introduced, it ought to come with as many of its improvements as is compatible with the country in which it appears.

But before launching into the expenses entailed by a higher standard of cultivation, it will perhaps be necessary to bear in mind that it is entirely beyond the reach of the natives until they shall find a landlord who will clear and prepare the land for them; the cultivation then, for the present, must be confined to the capitalist in whose behalf the State should lead the way.

Nine-tenths of the land in Burmah available for highland cultivation is forest land, before a plough can be set to work, clearing, draining, and levelling are indispensable. On high lands the same crops cannot with profit be grown year after year. A farm for instance, which shall be nothing but a tobacco farm will not survive long—there must be a rotation. A certain crop requires or exhausts a particular plant food, this must be supplied or replaced. We must beware of imitating the wasteful system pursued in India, which instead of bettering, empoverishes the ryot. Cattle which are to work comparatively heavy soils, must be fed on something better than the rank grass generally found at working times. Irrigation will often become a necessity. These elements of agriculture being admitted, the course to be pursued is obvious.

Let an experimental farm be started and conducted on rational and accepted principles, let it be supplied with implements of husbandry most likely to ensure cheapness and economy of labour, and it will begin a work which cannot but tend to be greatly beneficial in a country where enterprise is generally guided by example. Native agriculture too cannot but be greatly benefited, for if portions of the land thus brought under cultivation be let to cultivators, they will very soon with our crops adopt our system of tillage.

The Burmese are better off than their Indian neighbours, nor are they imbued with their prejudices; they are an imitative race, and they only require to be shown the way. These circumstances make improved agriculture simply a question of time in Burmah, if the proper impulse be given.

E. M.

EDITORIAL NOTES.

We beg to draw attention to the fact that the present number commences a new volume.

We have the pleasure in drawing attention to an interesting article on Himalaya *Lepidoptera* to be found in another column. Mr. de Nicéville has kindly promised us a few more articles of a similar nature, having reference to other portions of India, we are sure a large portion of our readers will take an interest in this enticing subject. We are deeply indebted to our correspondent for the trouble he has taken in placing these notes at our disposal.

In our August number we reproduced and made an editorial note on some queries of Mr. W. B. Smith, which he put in the *Journal of Agriculture* Franklin Co., Mo. In that note we left Mr. W. B. Smith to be dealt with by his own countrymen, many of whom we said were something more than *practical* farmers. Professor G. C. Swallow has replied to Mr. Smith's queries in a manner which we think highly satisfactory. The worthy Professor says "he has little sympathy with our comments." Well, probably had he seen as much of *practical* farmers as some men have, he would have been as severe as we were. However, the Professor's answers have justified our expectation, and we may add that if we have mistaken the spirit of Mr G. C. Smith's questions, it arose from no desire on our part to "burke" inquiry or withhold information.

We are pleased to observe that our old friend at Kotegurh is continuing his interesting notes this year, we are much indebted to him for this popular series of papers.

A practical paper in "Agriculture in Burmah" has been forwarded to us by an esteemed correspondent, from whom we shall be glad to hear further. He is in a position to know thoroughly what he writes about, and his paper gives evidence of his not writing as an official who draws his knowledge from a study of blue-books, but as one who understands from practice what he treats of.

The number of *The Indian Tea Gazette* for 5th December, commences, volume VI., and we have much pleasure in noticing the continued progress this useful publication is making. It is more and more becoming a medium of communication among tea planters, and if these gentlemen would second the efforts of the editor by taking a more lively interest in its success, it would become still more serviceable to them than ever.

It will interest our readers to know that the highest price ever obtained for indigo so far, was at Messrs. William Moran & Co.'s sale yesterday, when 23 chests of the well-known mark G H G—S realised an average of Rs. 350, and 12 chests of G H G—B an average of Rs. 374 per factory maund, the indigo being the outturn of the Sugrampore Concern in Bhagulpore. The first 10 chests of the G H G—B mark fetched no less than Rs. 377-8 per factory maund!

Tea and Coffee, &c., in France.—In 1876 the import of tea was 2,498,077 kilogrammes, of the value of 7,494,231 francs. The coffee imported was 87 million kilos. The consumption reached 53,471,000 kilos. The rest was exported. There are in France 248 factories of chicory; the total production is 18,546,595 kilos. There were made in France in 1876,20 million kilos. of chocolate of the average price of 2s. 10d. per kilo., or a total value of 64 million francs. About 10 million kilos. of cocoa were imported.

Railway Sleepers.—According to the various official reports of the most recent date, the gross number of sleepers required for the railways of the world is set down at 250,000,000. Taking the life of a sleeper at an average of some eight years, and allowing for the large increase of mileage every year, it would appear that above 45,000,000 of sleepers must be the annual requirement—or, making a deduction of about 5,000,000, on account of many railroads being laid with cast and wrought iron sleepers, the yearly destruction now going on may, it is thought, be fairly calculated at 40,000,000. These contain, on an average, about two and one-half cubic feet of timber in each sleeper, or about 100,000,000 of cubic feet, and, even at the most moderate estimate of their value, an enormous sum is thus annually expended, and a vast industry represented, in this single item.

In a communication from the Secretary to the Government of Victoria, Australia, to the Government of Madras, dated 29th March 1879, the subject of the importance of wattle-bark is discussed, and if the subject of tanning material is of sufficient importance to engage the attention of the Australian authorities, it is of much greater importance to us, who import leather goods so extensively, while we have all the raw material for our own supply within ourselves. The wattle, of which there are several sorts, principally belonging to the *Acacia* and *Eucalyptus* families, grows freely on swampy land, and on the borders of creek and water courses, and surely one could manage to cultivate it here, where there are many marshy localities. During the eight months ending 30 June 1878, the Colony of Victoria exported 11,378 tons of wattle-bark valued at £85,903, being at the rate of £7-11-0 per ton, or say Rs. 2-13-0 per bazaar maund. A communication on the subject, attached to this report, from the pen of Colonel Beddome tells us, that several species of the tree grow freely on the Nilgiris and Palneys, as also the fact that the bark of these trees if carefully cured here, is worth £5 to £6 per ton in England. We trust this subject will receive careful attention.

The order of the Government of Madras, on the working of the Saidapet Farms or the year 1878-79 is published, in which the results of the many experiments tried are spoken of, generally with approval. In tobacco, the old result followed; very superior leaf was grown, but the curing was a failure, when will it strike the Government that they must import exports, if they are ever to succeed in this. When the tea industry commenced in India, planters brought round from China as many professional tea-makers as were necessary to instruct the natives. Had they not done so, but tried experiments in their own way, they would not now occupy the proud position they do as the makers of the best tea in the world. Speaking of the ploughs tried which were the Swedish and American sorts, as also two of Collins's, the report says that the latter "did not work satisfactorily, but they are capable of improvement." It seems to us the mistake regarding these ploughs is, that they are in general too heavy for the cattle of this country. Have the managers of this farm tried the Jones plough. Mr. Jones of the Muir Mills, Cawnpore, has made one which we noticed in our last volume, page 260. We have seen it, and think it the very thing that India wants. Instead of introducing a plough new and strange to the conservative India rayat, Mr. Jones took the common country implement, and by making a few simple alteration and improvements, he succeeded in making a plough, which the rayat can carry on his shoulder, and which will be very effective in the field we are convinced.

Mr. A. O. Hume has reprinted here and in England his "Hints on Agricultural Reform in India," which was reprinted during the past summer for private circulation in England, and was actually in type, when, as the author says, the Government emphasized many of the remarks that it contains by abolishing altogether the Department of Agriculture. In an introductory note Mr. Hume says of the disestablished department that it has never "been able to effect much where agriculture was concerned, but it was working in a right direction; it knew what was required, and from time to time, when allowed a chance, did a little good on its own motion, or supported and assisted the efforts of others in this direction. So long as it existed, there was always some one at the head-quarters of the Government of India who possessed a knowledge of these subjects, and was at hand to support and advocate the sanction of all reasonable and practicable projects for improving in any way, however humble, the agriculture of the country. So long as it existed, there was always a hope, that amid the vicissitudes to which public affairs are subject, some lucky turn of the wheel might bring more enlightened ideas on these subjects into vogue, and thus render possible its conversion in a real working Agricultural Bureau. All this has passed away, and the only hope for India now lies in the chance that the real bearings and vital importance of the questions herein discussed may be better understood and appreciated in England than they have ever been, since Lord Mayo's death, by those in power in India." If report is to be believed, Lord Lytton has merely accorded a cold assent to the abolition of the department.

In reviewing the annual report on Labour Immigration into Assam during 1878, the Government of India has the following remarks on the increase in the number of desertions. Of Act VII, coolies, 3,954, or 5·29 per cent. on the actual strength absconded; and the desertions amongst coolies not under the Act were 3,561. The total for the province was thus 7,515 of all classes, as against 4,724 in 1877:—

The Government of India have hitherto considered that no special measures should be taken to check this evil, and have looked to the improvement of communications and the fuller supply of labour thereby afforded, as promising in due time its diminution. In consequence of the state of the finances, it has been necessary to forego, for the present, the Chief Commissioner's scheme for continuing the Northern Bengal Railway from the Teesta to Dhubri, and for establishing a service of Government steamers on the Brahmapootra from Dhubri to Dibroogurh. He has been asked, under these circumstances, to take up the question of improving the present route, and to endeavour to induce the Steamer Companies to run their vessels, during the immigration season, with greater punctuality and speed. Notwithstanding the excessive number of desertions now reported, and the unavoidable postponement of the more effective schemes for facilitating immigration, the Chief Commissioner does not ask for any reconsideration of the decision already arrived at. He observes that, although a mutual determination amongst the planters to inquire into the antecedents of new arrivals, and cordial co-operation in arresting offenders, would go far to suppress desertion, the great losses of the year under review have not induced the planters to take united action. Such combination has been prevented by conflicting interests, and the planters who from position and superior intelligence would lead the movement, suffer least, as the better management of their gardens reduces the number of desertions. This view of Sir Steuart Bayley is accepted by the Governor-General in Council. A high desertion-rate follows a high death-rate; and the year, was very unhealthy. Absconders were most frequent amongst the North-West coolies,—a class whose mortality was lamentably severe. It is shown that the more remote the district, the lower the desertion-rate, that in the nearer and more populous localities desertion is easier and discovery more difficult, and that thus, as a general rule, desertion decreases as the Brahmapootra Valley is ascended. But eliminating these special causes, it is found that within each district desertions are greatest amongst the classes which exhibit the heaviest mortality. The loss to the planting body, though it can easily be stated at a high figure on the assumption that deserters leave the province, is probably not really great, as deserters from one garden or district re-engage elsewhere. There is no reason, the Government of India think, to interfere on

behalf of the cooly. The panic which drives him from a garden where his comrades sicken and die may often be no more than the normal result of the instinct of self-preservation. The planters may be presumed to understand their own interests, and until they represent that action is required, it seems unnecessary for Government to move in the matter.

HIMALAYAN LEPIDOPTERA.

(By Lionel de Nicéville.)

NOTES on the Diurnal Lepidoptera taken at Kotgarh, N.-W. Himalayas, from 28th September to 6th October 1878, and from July 31st to August 13th, 1879.

The following insects were principally taken in the bed of a stream which crosses the road between Kotgarh and Komársen, about 1,000 feet below the station of Kotgarh, which itself is but a poor collecting ground, it being situated about midway between the valley of the Sutlej and the top of the range of hills on which it stands. Those insects that were taken in any other place are so noted.

NYMPHALIDÆ.

Danais, *Latr.*

D. Limniace, *Cram.* Very common on both occasions. It has, like the rest of the genus, a somewhat weak, flapping motion, but when disturbed, can make good use of its wings. Expanse from 3·8 in. to 4·2 in.

D. Plexippus, *Linn.* Also common. This is a very widely distributed insect, met with everywhere in the plains, and extends some distance into the interior of the Himalayas. Expanse from 2·8 in. to 3·6 in.

D. Chrysippus, *Linn.* Even commoner than the two preceding, and met with throughout India, and extends even into Europe. Expanse from 2·5 in. to 3·3 in.

Euplœa, *Fabr.*

E. Core, *Cram.* An exceedingly plentiful insect in Calcutta during the cold months, and occasionally met with in the hills in the autumn. It has a slow, weak flight, and continually settles. Expanse from 2·7 in. to 3·8 in.

SATYRINÆ.

Zophoessa, *Westw.*

Z.———*n. sp.* I first came across this butterfly on the Jalauri Pass leading from the Kulu to the Simla district. I next saw it in the thick forest between Kotgarh and Narkunda. Colonel A. M. Lang, R.E., to whom I have submitted my specimens, tells me that it is an unnamed species. All my specimens I took at rest on the red flowers of a Persicaria. Expanse from 2·1 in. to 2·2 in.

Lethe, *Hübn.*

L. Neelgheriensis, *Guér.* This genus seems particularly partial to the shade, and this species is no exception to the rule. Very common amongst trees and bushes, very seldom venturing into the broad sunlight. Expanse from 2·1 in. to 2·5 in.

Rhaphicera, *Butl.*

R. Moorei, *Butl.* I took one specimen of this insect near Narkunda, on August 13th, 1879. I have also one specimen from Murree. Expanse 2 in.

Maniola, *Schrank.*

M. Scanda, *Koll.* Common amongst long grass during the summer and early autumn months. It has a weak, pitching flight. Expanse from 2 in. to 2·1 in.

M. Annada, *Moore.* W. F. Kirby in his "Synonymic Catalogue of Diurnal Lepidoptera," gives this insect as a synonym of M. Scanda, but I am inclined to agree with Mr. F. Moore that it is a distinct species. It has the same habits and appears at the same time as M. Scanda. Expanse from 2 in. to 2·7 in.

Satyrus, *Latr.*

S. Schakra, *Koll.* This insect is to be met with at all seasons and everywhere in the N.-W. Himalayas, flitting along rocky roads and paths, and continually settling on stones, &c. I have taken it in Kashmir and far up into Ladakh. Expanse from 2 in. to 2·3 in.

Hipparchia, *Fabr.*

H. Parisatis, *Koll.* I took a few very worn specimens in October, 1878. Common this year in Chumba on grassy hill sides end of May, met with along the banks of the Chandra Bhaga River near Kushtooah, Kashmir, in June, and late in July near Bajoara, Kulu. It has a very strong, soaring flight, and is by no means an easy insect to capture with a precipice on one side, and the hill on the other rising at an angle of about 45°. Expanse from 2·6 in. to 2·8 in.

H. Brahminus, *Blanch.* Very plentiful during the rains, and met with almost everywhere. Like the rest of the genus it always settles on the ground with its wings closed, and then shuts the upper wings into the lower ones, so that only the lower wings and the extreme tips of the upper are visible. Expanse from 2·4 in. to 2·7 in.

H. Saraswati, *Koll.* This insect was exceedingly plentiful along the roads and pathways about Kotgarh this August. Its habits are exactly those of Brahminus. Expanse from 2·7 in. to 2·8 in.

H. Padma, *Koll.* This is the first insect of these last three to come out in the Spring, and is also the largest of the three. It has also a stronger and more soaring flight. Worn specimens are to be met with late on in the rains. Expanse from 2·9 in. to 3·6 in.

Ypthima, *Hübn.*

Y. Sakra, *Moore.* Common throughout the rains in grassy meadows and on hill sides. All this genus have a very weak flight and are given to continually settling. Expanse from 1·7 in. to 1·9 in.

Y. Philomela, *Joh.* The above remarks apply equally to this insect. Expanse from 1·4 in. to 1·5 in.

Atella, *Doubl.*

A. Phalanta, *Dru.* Very common in the plains during the winter months, and fairly so in the hills during the autumn, where it is generally to be met with near water. Expanse from 1·7 in. to 2·7 in.

Argynnis, *Fabr.*

A. Childreni, *Gray.* This is the most handsome and has the strongest flight of all the Himalayan Fritillaries. It first appears about June, and worn specimens may still linger on till late in September. Like the rest of the genus, it is very partial to thistles, and can be easily taken when busily engaged in sucking up the honey of these flowers. It also occurs in the Chumba State, Kashmir and Kulu. Expanse from 2·9 in. to 3·3 in.

A. Kamala, *Moore.* Fairly common throughout the North-West Himalayas and also in Kashmir. I have seen dozens of males (the females of all butterflies I believe, and as far as my experience goes do not similarly indulge) sucking up moisture in damp spots on the borders of streams in Kashmir in June. They are also very fond of compositæ. Expanse from 2 in. to 2·7 in.

A. Niphe, *Linn.* This insect is apparently double brooded, as I took small but quite perfect specimens at Jutogh near Simla on April 11th, 1879. It has a second brood, which is by far the most plentiful, about June. I have met with it only on the tops of bare hills, flying backwards and forwards and occasionally settling, and then baffling with the wind that is generally rampant in such places. The females are very much scarcer than the males, probably they fly but little. Expanse from 2·1 in. to 3·3 in.

A. Issæa, *Moore.* Kirby gives this insect as a synonym of the European A. Lathonia. There is hardly a month in the year when this hardy and apparently multi-brooded insect is not to be met with. It seems to have an antipathy to water: grassy hill tops and sides, particularly where the "wild thyme grows" seem its favorite grounds. Expanse from 1·9 in. to 2·1 in.

Symbrenthia, *Hübn.*

S. Hyppoclus, *Cram.* Fairly common in the beds of streams during the summer and autumn. Expanse from 1·6 in. to 2·1 in.

S. Hypselis, Godt. Not nearly so common as the above. I has a habit of flying backwards and forwards in a narrow gorge between rocks in one of the mountain streams so common in the Himalayas, and occasionally settling on the over-hanging foliage. Expanse from 1·5 in. to 2 in.

Vanessa, *Fabr.*

V. Charonia, *Dru.* This beautiful insect is generally to be met with in the beds of streams, though I have taken it on the very tops of hills, very far from any water. It frequently settles on the trunks of fir trees if there are

any near, where, with closed wings it is almost invisible, the dark shaded markings of its under-wings exactly assimilating with the bark of the trees. It also very frequently takes up a "beat" in the bed of a mountain stream, up and down which it continually flies, but always returning to one stone on which it settles, however often it may be disturbed. Expanse from 2·2 in. to 2·9 in.

V. KASHMIRENSIS, *Koll.* Kirby gives this also as a synonym of the European V. Urticœ. This insect may also be met with on fine days from January to December, it has several broods, and like its European cousin, feeds on the common stinging nettle. It is certainly a much darker colored insect than the home one, and I think deserves to be called a different species. Expanse from 1·9 in. to 2·3 in.

V. XANTHOMELAS, *Wien.* By no means a common insect, I have taken a few at Simla, again at Kujeah, near Dalhousie, in May, and at Ulwas, near Pangi, a little later on. In Kulu it feeds on a bush called by the natives "Kukkurree." Expanse from 2·5 in. to 2·8 in.

Pyrameis, *Hübn.*

P. INDICA. *Herbst.* This insect is generally known in India by Miller's name, P. Callirhoë. It is very common in the late summer and autumn months throughout the N.-W. Himalayas, and hybernated specimens are met with in the spring. Like its English cousin the "Red Admiral" it feeds on nettle. Expanse from 2·1 in. to 2·7 in.

P. CARDUI, *Linn.* This is one of the first insects you will meet with in the Spring, and the last you will see in the Autumn. It is an early riser, and one of the last to go to bed. I have actually watched them follow the setting sun as its beams gradually ascended the hill side, caused by the sun setting behind an opposite range of hills. I have taken specimens in the plains as far east as Dinapore, but I have never seen any in Calcutta. It also occurs commonly in Kashmir, and I have taken it high up in Ladakh. Expanse 2 1 in. to 2·6 in.

Junonia, *Hübn.*

J. LEMONIAS, *Linn.* Equally common in the plains and in the hills, in the latter it is most frequently met with in the beds of streams. Expanse from 1·7 in. to 2·2 in.

J. ŒNONE, *Linn.* This insect affects paths, rocky, bare hill sides, the beds of streams where they widen out into stony expanses of sand and boulders, and similar places devoid of vegetation. They are hard to catch, flying off on one's approach and settling on a stone or rock a few yards ahead, and on again coming near, the same performance is repeated. It was common at Kalka in October 1877, and I took it in the Botanical Garden and nowhere else in Calcutta, in December 1878. Expanse from 1·8 in. to 2·3 in.

J. ORITHYA, *Linn.* Generally seen in company with the preceding; it also closely resembles it in habits and time of appearance. Both are to be met with on the wing in the hills from March to November. Expanse from 1·4 in. to 1·9 in.

J. ASTERIE, *Linn.* In Calcutta I have taken this insect all through the winter in gardens, on the borders of tanks, &c. In the hills it is far more scarce, I have only taken it occasionally just after the rains in the beds of streams. Expanse from 1·9 in. to 2·3 in.

J. ALMANA, *Linn.* A commoner insect than Asterie, and met with in similar places and seasons. Expanse from 2 in. to 2·4 in.

Precis, *Hübn.*

P. IDA, *Cram.* This insect is more generally known as P. Iphita, which Kirby gives as a synonym of Ida. Common all the summer and autumn in the beds of streams, and occasionally met with on hill tops far away from any water. Expanse from 2·3 in. to 2·7 in.

P. VEDA, *Koll.* Generally known in India by Moore's name of P. Hara. It is much rarer than Iphita, and I have only seen it near water. Each insect seems to frequent a limited space, and flies backwards and forwards within this space, occasionally settling on overhanging bushes, &c., but starting off in pursuit, and doing battle with any intruder, especially one of its own species, that dares to invade its domain. It soon becomes shattered, and no wonder considering its pugnacious temperament, so it is not easy to secure a perfect series. Expanse 2·1 in. to 2·4 in.

Cyrestis, *Boisd.*

C. THYODAMAS, *Boisd.* This beautiful insect, very appropriately called, "the map" by school boys, is frequently to be seen soaring backwards and forwards in some mountain stream with richly wooded sides. It frequently settles, often with widespread wings on a quartz rock, where, by reason of its coloration and markings, it is almost impossible to see. It has also a habit of suddenly settling on the *underside* of some broad leaf overhanging the water, with wings wide outspread, a feat of gymnastics I have never seen any other butterfly accomplish. It is on the wing from early summer, and I have taken perfect specimens as late as the middle of November at Simla. Expanse from 2·2 in. to 2 4 in.

Stibochiona, *Butl.*

S. NICEA, *Gray.* I took two very dilapidated specimens last year, and two—one only just out—this year. It has a somewhat bold flight, but settles with wings wide open on trees and bushes, and is then easy to capture. It does not seem to occur at Simla, but I have Darjeeling specimens. Expanse from 2·5 in. to 2·8 in.

Hypolimnas, *Hübn.*

H. BOLINA, *Linn.* I first saw a specimen of this insect at Kotgarh last year in the remorseless clutches of a large green Praying Mantis, subsequently I took several specimens. For so large an insect, it has not a very powerful flight, and is easy to capture. It is common in gardens, &c., in Calcutta during the cold weather. My specimens do not differ in size very much, I have seen some from Central India however quite half the size of my largest specimen. Expanse from 3 in. to 4 in.

Neptis, *Fabr.*

N. AMBA, *Moore.* Rather uncommon, and always met with in the beds of streams. It seems double brooded; I have taken specimens early in the summer and again after the rains. Expanse from 2·2 in. to 2·8 in.

N. NANDINA, *Moore.* This insect seems to affect a wider range of country. I have taken it most frequently near water, but also on hill tops. Occurs late in the autumn, but probably there is an earlier brood in the summer. Expanse from 2·2 in. to 2·5 in.

N. ACERIS, *Lep.* To be met with everywhere where there are trees, and at all seasons of the year. Like the rest of the genus it has a very beautiful, floating flight, it is a particularly pretty sight to observe two of these insects courting, they fly round and round each other making endless circles in the air, and with so little apparent exertion, hardly moving their wings at all, they always seem to be spread wide open. Expanse from 1·5 in. to 2 4 in.

Athyma, *Westw.*

A. OPALINA, *Koll.* I have taken perfect specimens of this insect from March to November, so it must be poli-brooded. It has a very swift flight, but often settles. It is met with everywhere from the bottoms of the valleys to the tops of the hills. Expanse from 2·2 in. to 2·7 in.

A. ASURA, *Moore.* I took 3 specimens of this insect at Kotgarh in October 1878, and have never come across it elsewhere, so I consider it a rare insect in this part of the N.-W. Himalayas. Expanse from 2·5 in. to 2·9 in.

Nymphalis, *Latr.*

N. ATHAMAS, *Dru.* I took one specimen in October 1878, at Kotgarh, imbibing moisture on a damp spot near the Komársen stream. Of all the butterflies I am acquainted with this insect is the swiftest on the wing. I have taken a few small and apparently hybernated specimens on hill tops near Simla in April, and have *seen* the ordinary sized ones in various places near Simla in the autumn. My Darjeeling specimens are decidedly darker than those taken at this end of the Himalayas. Expanse from 2·2 in. to 2·9 in.

(To be continued.)

OFFICIAL PAPERS.

ARTESIAN WELLS.

FROM

W. KING, ESQ.,
Deputy Superintendent, Geological Survey of India.

To

J. H. GARSTIN, ESQ., C.S.I.,
Acting Secretary to Government,
Revenue Department,

Dated Yercaud, 7th October 1879.

IN reply to the Order of Government (18th September 1879, No. 1,878), I have the honor to inform you that no suitable sites for artesian wells, properly so called, are known in this presidency to the Geological Survey of India.

2. The present inquiry having however risen out of the discovery of the gushing wells at Pondicherry, I venture to make some remarks on these for the information of Government.

3. I use the term "gushing wells" in this connexion because the Pondicherry wells are not yet shown to be artesian, it being quite possible that the gush of water may be caused by the pressure of the superincumbent strata (in one case 79·52 metres in thickness) on a confined stratum of water instead o f, as in a true artesian well, by the basonal water-stratum having a higher level at more distant area than that at the well vent. I myself do not recollect any higher environs of Pondicherry whence such a stratum of water could extend under the vent at the Jardin d' Acclimatation; hence I am led to speculate on the possibility of superincumbent pressure.

4. So far there is no direct evidence as to why these gushing wells should occur at Pondicherry. The first well, that of M. Charles Poulain, was struck, as it were, by chance, and the next under the Colonial Engineer was taken at random. The chances are that such wells may be struck on the Madras alluvial plot, or indeed anywhere else along the Coromandel alluvial border; the desideratum in any case being, according to my view, that they should be bored to a sufficient depth to ensure a good pressure of overlying strata.

5. The fact remains, however, that wells having a gush over surface level have been struck at Pondicherry; hence it may be assumed that there is a possibility of striking the same kind of water sources on any alluvial stretch similar and similarly placed to that of the French possession. In some respects the Madras alluvial plot agrees with that of Pondicherry; as, for instance, below the Red Hills, though the Cuddalore, Nellore, and Cocanada plots are much more similarly placed in regard to adjacent high-ground.

6. My own recollection of the Pondicherry plot only allows me to carry the comparison so far, but it is possible that were I to revisit that ground, I might be able to run the argument closer. Should the Government approve of my visiting Pondicherry for this purpose, my services are of course at their disposal on my being placed in communication with the French Government at that station.

7. Experiments might certainly prove successful at the Government Farm at Saidapet or at the Horticultural Gardens, but as long as the search is one of mere guess-work, it is a question whether the development of this source of water-supply might not be left to private enterprise which in this way has been successful so far at Pondicherry.

REANA LUXURIANS.

FROM

The Director, Department of Agriculture and Commerce,
N.-W. Provinces and Oudh,

To

The Secretary to the Government of the
N.-W. Provinces and Oudh,

Dated Cawnpore, 26th November 1879.

SIR,

In continuation of my No. 253, dated May 21st, 1878, I have the honor to submit a report on the cultivation of Reana (euchlaena) luxurians in these provinces during the year 1878-79.

2. The introduction of this fodder plant into these provinces dates from the commencement of 1877, when I obtained a small packet of seed from the Agri-Horticultural Society of Calcutta. Although it could only be tried in that year on a very small scale, yet the results appeared to prove that the plant would flourish well in the plains, and would give an abundant fodder crop which was more liked by cattle and (from its sweetness) more nourishing than the usual crops grown for fodder in this country.

3. In March 1878, some more seeds were received from the Government of India which had been received from Dr. Schweinfourth, the Afr ican Explorer. The quantity was small but supplemented by the seed which resulted from the cultivation of the preceding y ear, enabled experiments to be conducted on a larger scale.

4. Seed was distributed to the Saharunpur Botanical Gardens, the Cawnpore Experimental Farm, the Lucknow Horticultural Gardens, and the Forest Nursery, Ranikhet, for careful sowing and cultivation. Some was also sent to canal officers for cultivation on the banks of distributaries, to the Ordnance Timber Agent, Fatehgarh, and to various European officials and native landholders who showed an interest in agricultural matters. Reports from some of these latter have not been received, nor is it considered advisable to insist in all cases on the submission of detailed information as to the result of this, or similar agricultural experiments. The trouble of keeping and submitting an accurate Register of results might debar this department from the co-operation and assistance of private persons for whose benefit the experiments themselves are intended.

5. The reports which have been received may be taken to prove that the Reana Luxurians is a most successful fodder crop in the plains and on irrigated land. In the hills (judging from the report of the Superintendent, Forest Nursery, Ranikhet) it will not succeed, and it is only when plentifully watered that it grows with the luxuriance which makes it one of the most prolific of fodder crops. Under favorable conditions the plants grow to a height of over 15 feet, with as many as 30 stalks from a single root. It will give three cuttings between August and November. The quantities of seed which can be distributed were very small, in most cases not more than 1 oz., since there is a large demand for seed it was considered advisable to grow the plant for seed, and not as a fodder crop, and there are no definite statistics of the amount fodder produced *per acre*, since the plants were in no case systematically cut down. The return in seed was very large, the plants at Lucknow yielding 1 maund from 1 oz., or 1,280 fold. The green stalks and leaves are greedily eaten by cattle and elephants.

6. During the past year, sufficient seed has been raised for the cultivation of Reana during the pr esent year on a large scale to give definite results as to its outturn in fodder, compared with the native fodder crops.

SALARU EXPERIMENTAL FARM.

No. 3834 of 1879.
Revenue Department.

FROM

COLONEL L. DUNSTERVILLE,
Collector and Magistrate of Hyderabad,

To

THE COMMISSIONER IN SIND,
Hyderabad Collector's Office,

Dated, 22nd October 1879.

SIR,

I HAVE the honor to forward herewith the report of the farm at Salaru, for the half-year ending 1st October, with a statement of income and expenditure from 1st April to 30th September inclusive.

2. Mr. Strachan's letter is dated 28th September (it should have been dated 1st October). It reached me on the 4th instant, but was returned for amendment as the report of the Economic Garden (which will shortly be separately submitted) was mixed up with it.

3. It will be observed that, as was the case throughout the province, the season was later than usual this year, the rising of the river being greatly delayed by the want of rain in Upper India, whilst the mildness of the winter deprived us of the early "freshes" which come down as soon as the snow begins to melt,

the mass deposited below the line of perpetual snow being insignificant compared with that of ordinary years.

4. Another cause for the lateness of the season in all the Northern talukas of this districts is, the visitation of locusts which devoured seedling cotton and cereals (in some instances, more than once) as soon as these appeared above ground and the Salaru Farm formed no exception to the rule.

5. The inundation showing, in its earlier stages, every sign of being an unusually low one, the cultivators in the neighbourhood of Salaru and elsewhere ventured to cultivate the low-lying lands left by the river, and which are usually cultivated with spring crops (rabi) after the river has receded. Later on, the river rose rapidly and attained the height of 19 feet 7 inches on the gauge at Kotree (½ an inch higher than last year's maximum) and the result was that the whole of this cultivation was submerged and destroyed.

6. The result of the experiments detailed in paras. 5 and 11 of Mr. Strachan's letter will form the subject of the next half-yearly report.

7. I shall be glad to receive and submit the report and proposals of Mr. Strachan for utilizing the wind as a motive power for raising water. I had some conversation on the subject with the Hon'ble Col. Anderson on his visit to Sind in the spring, and he promised to get me some information, but I have not since heard from him. Probably, he has not been able to meet with machinery cheap enough and simple enough, for our requirements.

No. 90 of 1879.

FROM

The Superintendent of Cotton Experiments,

To

COLONEL L. DUNSTERVILLE,

Collector of Hyderabad, Sind,

Superintendent of Cotton Experiment's Office Camp,

Salaru, 28th September 1879.

SIR,

I HAVE the honor to forward the following half-yearly Report, in compliance with Government Resolution No. 2188, dated 24th April 1879, and your endorsement No. 1455 of 3rd May 1879.

2. What is past of the current season has been chiefly characterized by severe hail-storms in the beginning of May. Late flooding of the river, and an almost total want of rain in July and August. The first and last remarks I believe apply only locally. Our total fall of rain since May is only 89 cents. which fell on 30th June, July 2nd, and August 18th. During July and August there was a good deal of cloudy weather which was very beneficial to the young plants, and prevented the rapid evaporation which goes on during clear weather. Locusts were very plentiful and did a good deal of damage on several of their visits.

Water came into the Mahmood Ghora on the 8th or 9th of June, but fell almost immediately after, so low, that it could not be got into the wheel channels, till the 23rd of the month, on this account cotton has been less sown on this canal this year than is usually the case, and grain more extensively. Since the 22nd of the current month the water is again very low, and we are now obliged to work a double lift to get it on to the farm.

3. Crops in general in the vicinity of Salaru are good, the cotton is in some cases rather later than it should be, but the plants are good, the grain crop will be very good if locusts do but keep away till it can be harvested. On the kurrias or small canals the grain crop is more backward, being late in being sown, it will not be possible to give it sufficient water to bring it to be a good crop. In many cases the cultivators are themselves to blame for being late, for the water was up to their wheels some time before they began to work them, and as they sow little but *bajri*, three months' water should have enabled them to, at least ensure a fair crop. All the crops in the *katcha* (low land along the banks of the river) were destroyed by the high flood we have had this year. The crops anywise largely grown in this neighbourhood during the inundation season, are cotton and grain; chiefly *bajri*, any other crop grown, occupies but a very limited area compared to these two.

4. We were unable to begin watering till the 23rd of June, by which time the cotton seed should have been nearly all in the ground—on this account my cropping arrangements were considerably upset and some of my experimental too. The different crops and the areas sown with them are as under :—

	Acres.	Goontas.
Sind Cotton	8	14
Sorghum Sacharatum	1	0
Red seeded Jowari	1	27
Bajri Penicillaria Spicata	20	1
Guar (1)	0	14
Tobacco	0	22
Nanguli	0	9½
San	0	20
Oord ka Dhal	0	10
Tir	0	10
Total area sown ...	33	7½

5. The experiments undertaken this year are as follows :—

I. Sind cotton on limed and on unlimed land, the object being to ascertain whether an application of lime would be beneficial to land in this neighbourhood.

II. Guar (a kind of pulse) used as a vegetable in the green state, but grown chiefly for camel feed on limed and unlimed land, object the same as the preceding.

III. *Bajri* sown and transplanted to ascertain which process will give the most profitable return.

IV. *Bajri* manured with farmyard manure and with brick-kiln rubbish, to shew whether the latter be valuable as a manure, the substance being at present pretty plentiful in this neighbourhood and entirely unused. The foregoing four experiments are in duplicate, the remainder are single.

V. San (Panicum frumentaceum), Nanguli (Elensine Coracana), a continuation of last year's experiment with these crops on khullur land.

VI. An acre of each of the five varieties of *bajri* referred to in previous reports, was sown between the 15th and 20th July, to ascertain which of them would be best for cropping here. At present they are all good crops and seem very equal. Each plot has been treated the same as to manure, ploughing, and watering the crop will be ready for harvesting in about ten days hence.

VII. *Oord ka dhal* to try how the plant would thrive here. The seed was obtained in the Hyderabad bazaar and sown on the 17th August, the plants are doing fairly well; the plot was limed last year, and manured with farmyard manure this season previous to the seed being sown, the young plants were once needed. Of these two experiments VI. and VII. I shall not say more at present. On the others I offer the following remarks.

6. The experiments on limed and unlimed land is a continuation of an experiment commenced last year, and one which would require to be continued over a series of years before definite results be obtained. The original areas was two acres, but on account of the end of the field adjoining the Mahmood Ghora having been last year pitted and partially washed away, the area sown with cotton is 1-10 goontas, and that with guar 14 goontas. During the cold weather the land was lightly ploughed with the English plough to get quit of the grass weeds, which last damp season caused to over-run it while under a *bajri* crop. The whole was manured with farmyard manure, and cross-ploughed with the Sindi plough at the time of sowing. At the present date I cannot say which (the limed or unlimed) is the best crop, both are good, the plants being over 5 feet high and well branched. The guar is an unusually luxuriant crop, and is to all appearance equally good on the unlimed as on the limed land. Both fields have been irrigated five times and the cotton twice weeded. If the cold weather do not set in too early, the latter will be a very heavy crop.

7. *Bajri* sown and transplanted, half an acre was sown on the 6th August and the same area filled up by transplanting on the 27th August. The land in other respects has treated the same

[illegible] sown plots. It was manured with farmyard manure and once ploughed at the time seed was sown. The sown portion is at the present time the best crop. The transplanted area has filled up well, and the plants are good but too late to give a full yield—some portions are only beginning to show the ear, some of the spikes are of good size, but not what I expected they would be, judging from what I have seen of them where early transplanted to make up blanks in ordinary fields—in such cases I have found both the spike and the grains larger than on the sown portions, and in the present instance, I account for the apparent failure by the operation of transplanting having been done too late in the season.

8. *Bajri* on land manured with farmyard manure and brick-kiln rubbish, ½ an acre of each. The kiln rubbish contains a considerable quantity of wood-ashes, and a little ash of cow-dung, the remainder is lightly burnt clay in a powdery state. The one-half acre got 160 ass-loads of this compound, and the other 178 ass-loads of farmyard manure, culture in other respects has been the same for both plots, both were sown on the 7th of August, at the present time it is not possible to detect anything more favourable in the one than in the other, both are very equal fair crops, the plants on the rubbish manured land has a slightly darker colour than those on the farmyard manure plot, but even in this the difference is little at any rate,—so far as this experiment has gone, it shews that such rubbish may be made useful as manure instead of being left about in unsightly heaps often in the midst of cultivation, and where other manure is difficult to obtain. I have seen none of it used by the natives here. The ashes probably hold the chief active elements it contains, but the soft burnt powdery clay is also likely to be beneficial mechanically, if not chemically. It may be burnt too much to be easily soluble, consequently it may be almost inert in furnishing plant food.

9. San (Panicum frumentaceum), and nanguli (Eleusine Coracana), on salt or khuller land is a continuation of an experiment commenced last year, and the result is as yet much in favour of the nanguli, which is about equal to last year's crop in appearance, while the sand is inferior to what it was last year. The nanguli is the only crop I know of worth growing on such ground, and it would no doubt exhaust the soluble saline matter sufficiently in course of time to fit the ground for producing other crops of more value. It could however only exhaust what is within reach of its roots, and this would soon be replaced from deeper laying strata. The only really effective remedy would be drainage, and that would be rather expensive at the outset, and often from the low situation of the land inapplicable.

10. Sorghu and red seeded *jowari* were again sown this year, with the view of further testing last year's experiment with them, but they have been so damaged by pigs that I have given up the idea of considering them reliable for that purpose. On account of the jungle land along the river being flooded, the wild pigs took shelter in the cultivated fields, from which it is almost impossible to get quit of them, if hunted out during the day, they find their way back at night again. The *jowari* was sown on the 26th June, watered 4 times, manured with farmyard manure and once ploughed at the time of sowing. We are now nearly finished harvesting it, it is an excellent crop, but as already mentioned, very much damaged by swine. The sorghu was sown on the 27th June, treated in every manner the same as the *jowari*, it will not be fit to harvest for some 15 days yet. It is a good crop, but also damaged from the same cause as *jowari* suffered. There also appears to be a considerable number of hybrid plants in the field, there was none such in last year's crop. This is the first time I have observed any mark of hybridisation in the sorghu, but I believe it is, under circumstances favourable to that operation, prone to it. Last year being more than ordinary damp, and the sorgho and *jowari* growing and seeding side by side, I have no doubt but the mixture had taken place then through the agency of insects and the wind. Some of the hybrid panicles have seed more than twice the size of the original sorghu, and have less of the black shell which envelopes it, while in colour they are different from the sorghu or any *jowari* which was growing near it, being almost white.

11. Tobacco is a good crop this year all round Salaru. It is almost always grown by bunyas, and not very extensively by them, in this district few fields of it are over an acre and-a-half to two acres in extent. It is grown year after year on the same ground which is always heavily manured with goat droppings before the crop be transplanted. Transplanting is done here in August and beginning of September, it is taken in hand as soon as the *bajri* and cotton has been sown, and from that time till it be fit for harvesting in December or the beginning of January it requires constant looking after, in weeding, watering, and stopping, leading, or lateral shoots; 2,300lb. per acre of leaf (weighed after sweating when it is packed into bales (*pindees*), each weighing 2½ maunds) is a common yield; our last year's crop of 22 goontas (a little over half an acre) weighed as above 1,267lb. and was sold for Rs. 116-10-8 on the farm; the actual cost of producing it was Rs. 77-5-10. This year's crop on the same piece of ground seems as yet to be fully heavier than last year's. Were we to plant a new plot of land we would get but very little for, if in fact we managed to sell the produce of the first year or two's cropping. New land produces too mild an article for local sale.

12. Irrigation.—The quantity of water artificially applied to crops here is probably greater than in any other part of India. I give the following as an example. It shews the approximate depth of water our tobacco field had last year both naturally and by artificial means, each watering ordinarily is of a depth of fully 3 inches—the field got 8 waterings, equal to 2 feet, and during the growing season we had a rainfall of 18 inches 86 cents. which makes the total irrigation and rain water equal to a depth of 3ft. 6·86 inches supplied to the field between 6th July and 25th October. During the growing season, June, July, and August if the weather be dry and clear, cotton requires about three waterings each month to prevent it receiving any check in growth. It is but seldom people are able to water all the land they sow at the time the crop most wants it, and this makes the crop later in coming to maturity and the yield much less than would be the case were water applied when required. Especially is this the case with fields worked by Mahomedans; they sow a larger area than their means will admit of their working properly in any respect, and, as in this district where cotton is pretty extensively grown, the Mussulman mostly has a partner in raising this crop, or he lets the land to a bunya, he (the land owner) supplying bullocks for ploughing, and promising three waterings a month to the crop while it is growing, the bunya does all other work at his own cost, finds manure if the field get any, otherwise it gets a top dressing when convenience offers of Khuller from the site of some ruinous village, or swept from under a babul tree. The amount paid for the land is made to depend on the stipulated number of waterings being supplied, and for cotton ranges from Rs. 30 to Rs. 50 per acre for the season, provided it get three waterings monthly. It very often happens that the area so let takes the greater part of the water the cultivator can lift, and his grain crop suffers in consequence. During this season I have been devoting considerable attention to wind as a motive power for irrigating. It could not be depended on alone for raising water for any crop, but it would be of great assistance to the present means of irrigating. The main obstacle is the great expense of the necessary machinery. I believe that as the wind here, blows almost constantly during the inundation season from a southerly direction, and during the cold weather from the north, less complicated and much cheaper machinery than any generally in use, could be made to answer the purpose, wherever the wind blows with any regularity from two opposite directions, as is the case here. In the course of this season I will submit a further report on this subject, along with a model of the sort of machine I propose to try.

13. Cultivators are now commencing to clear land in the *kutcha* for winter crops, owing to so much land having been flooded, the *rabi* cropping has every prospect of being very extensive. Mutter and jumba are the crops first sown. Wheat will not be sown for some time yet.

14. During the season of 1878-79 we distributed very little seed for field sowing. During the current season we have disposed of the following quantities of seed:—

Cotton seed	126lb.
Bajri	231 „
Other seeds	11 „

Statement shows the expenditure and income on account of the farm for the past six months from 1st April to 30th September, both days inclusive.

EXPENDITURE. Description.	Amount. Rs.	A.	P.
On account of Farm Establishment	198	6	2
Do. Labourers' wages	842	4	0

Do. 13 maunds of bajri grain 1878-79 ...	50	7	3
Do. One piece of babul wood	8	0	0
Total Income Rs. ...	616	5	6

W. STRACHAN,
Superintendent of Cotton Experiments.

No. 4262 of 1879.

Revenue Department.

COMMISSIONER'S OFFICE,

Kurrachee, 29th October 1879.

Letter No. 8884, dated 22nd October 1879, from Collector, Hydarabad, with report on Salaru Farm.

SUBMITTED to Government—the date of sending in the Report, has been altered as required by Government Resolution No. 2188, dated 24th April last.

2. A very fair quantity of work appears to have been done on the farm at Salaru during the half-year ending 1st October 1879, despite the many difficulties encountered, such as the late rising of the river, the scanty rainfall, the visitation from locusts, and the submersion of crop from the rapid and high inundation later on.

3. The results of the experiments made in the use of lime as a manure are still, as they were at the time of the last report, uncertain, nor can it be said that the recorded results of any of the experiments teach much, though doubtless they are all valuable in their way. Mr. Strachan, like many before him, seems eager to to try wind as a motive power for irrigation purposes. This has been often tried, and has always failed, and Mr. Strachan would do well to devote his energies to matters less mechanical and more directly connected with agriculture.

H. N. B. ERSKINE,
Commissioner in Sind.

SELECTIONS.

OPIUM CULTURE IN AMERICA.

THE interest expressed by a high official of the Opium Department in the cultivation of the poppy in America, induced the Editor of the *Indian Herald* journal to apply to the Government of the United States for information on the subject. The following reply was received by the mail delivered this morning, together with statistical abstract, which we purpose examining in a more lengthy article.

Department of Agriculture, U. S.
Washington, D. C., *7th November*.

THE EDITOR OF THE INDIAN HERALD, ALLAHABAD,
N.-W. PROVINCES, INDIA.

SIR,—In response to your expressed wish for information concerning the poppy and the manufacture of opium in this country, it may be stated in general that the poppy has never been cultivated here for commercial purposes to any extent, and that the production of opium is comparatively trifling, while experience in several of our States has demonstrated that opium of good quality can easily be produced here.

Samples of opium produced in Tennessee, North Carolina, and New York, and even as far north as the State of Vermont, have upon analyses been pronounced fully equal to the average of the best imported.

In California the culture of the poppy has been somewhat largely introduced, and is being extended. The middle and southern portion of that State are thought by those who are familiar with opium culture, to be, in respect to both soil and climate, peculiarly adapted to the production.

The common garden poppy (*Papaver somniferum*) is the species cultivated here—the white seed variety being used for making opium, and the black seed for oil.

You will thus perceive that the cultivation of the poppy for medicinal purposes has not received in this country the attention which it deserves. Our supply of opium chiefly obtained from Smyrna, exceeds 450,000 pounds, and the total value of our imports is at least 2,000,000 dollars.—Respectfully, C. A. CARMAN, *Acting Commissioner*.

AN EXPERIMENT WITH PEARL MILLET.

MR. P. HENDERSON, a well-known New York gardener and seedsman, sends the following communication to one of our American exchanges :—

Pearl millet has been cultivated for some years as a forage plant in some of the Southern States as 'African cane,' 'Egyptian millet,' 'Japan millet,' and in some places as 'horse millet,' but little was known of it a the North before last year, and then only in such small quantities as to hardly allow of a fair trial. From what we saw of it in 1877, we determined to give it a thorough trial this season. A piece of good strong loamy ground was prepared as if for a beet or turnip crop, by manuring wit stable manure at the rate of 10 tons to the acre, ploughing 10 inches deep and thoroughly harrowing. The millet was then sown in drills 18 inches apart, at the rate of 8 quarts to the acre. We sowed on the 15th May, about the date we plant corn; in 12 days the plants were up so that a cultivator could be run between the rows, after which no further culture was necessary, for the growth became so rapid and luxuriant as to crowd down every weed that attempted to get a foothold. The first cutting was made July 1, 45 days after sowing ; it was then 7 feet high, covering the whole ground ; and the crop, cut 8 inches above the ground, weighed (green) at the rate of 30 tons per acre. This, when dried, gave 6½ tons per acre as hay. After cutting, a second growth started, and cut August 15, 45 days from the time of first cutting. Its height was 9 feet; it weighed this time at the rate of 55 tons to the acre (green), and 8 tons dried. The third crop started as rapidly as the second, but the cool September nights lessened its tropical luxuriance, so that this crop, which was cut on October 1, only weighed 10 tons (green) and 1½ ton dried. The growth was simply enormous, thus ;—First crop in 45 days gave 30 tons green, or 6½ tons dry; second crop in 45 days gave 55 tons green, or 8 tons dry ; third crop in 45 days gave 10 tons green, or 1½ tons dry ; the aggregate weight being 95 tons of green fodder in 135 days from date of sowing, and 16 tons when dried to hay. This exceeds the clover meadows of Mid-Lothian, which, when irrigated by the sewage from the City of Edinburgh, and cut every four weeks, give an aggregate of 75 tons of green clover per acre. There is little doubt that pearl millet is equally as nutritious as corn fodder, which it resembles even more than it does any of the other millets. We found that all our horses and cattle ate it greedily, whether green or dry. If sowing in drills is not practicable, it may be sown broadcast, using double the quantity of seed—say sixteen quarts per acre. The ground should be smoothed by the harrow, and again lightly harrowed after sowing ; if rolled after harrowing all the better. I know of no farm crop that will better repay high manuring ; but so great is its luxuriance that it will produce a better crop without manure than any other plant I know of. In those parts of the Southern States where hay cannot be raised, this is a substitute of the easiest culture ; and being of tropical origin, it will luxuriate in their long hot summers. Even though our northern seasons may be too short to mature the seeds, our experiments in New Jersey this summer show what abundant crops may be expected if similar conditions are secured. Pearl millet, as a *fodder plant*, presents a new feature in our agriculture, and I feel sure that within ten years we shall

wonder how we ever got along without it. Besides our own testimony given above, we have received the most satisfactory letters from experienced men in different parts of the country to whom we sent seeds of pearl millet for trial, and all are unanimous as to its enormous productiveness and great value. From all we have seen and can learn, we are fully convinced that pearl millet is to be one of the great fodder plants of the future.

TEA AND COFFEE IN THE UNITED STATES.

THE quantity of tea imported during the five years from 1854 to 1858, inclusive, amounted to 126,008,504 pounds, and during the five years from 1874 to 1878, inclusive, to 307,269,478 pounds, showing an increase of 181,265,969 pounds, but considering the increase of popula tion since 1858 this is not an excess quantity.

The quantity of tea imported from each country, irresp ective of the country of production, during the year ended June 30, 1878, was as follows:—

Countries.	Quantities.
	lb.
China, including Hong-Kong	38,325,184
Japan	23,938,734
The United Kingdom (England, Scotland, and Ireland)	3,027,624
British East Indies	18,518
Netherlands	14,793
Provinces of Nova Scotia, New Brunswick, and Prince Edward Island	14,547
Provinces of Quebec, Ontario, Manitoba, and the North-West Territory	13,027
Dutch East Indies	4,630
Hawaiian Islands	4,428
Newfoundland and Labrador	1,550
Belgium	1,389
Argentine Republic	1,114
Germany	846
British West Indies and British Honduras ...	225
France	100
Total	65,366,704

The United Kingdom, it is well-known, imports more tea than any other country, as the United States imports more coffee than any other country. From official statistics, it appears, that the co nsum ption of tea in the United Kingdom amounted to 4·56 pound *per capita*, during the calendar year 1877, and in the United States to 1·36 pounds *per capita*, during the fiscal year ended June 30, 1878; while, on the other hand, the consumption of coffee in the United Kingdom amounted to 0·98 pound *per capita* during the calendar year 1877, and in the United States to 6·55 pound *per capita* during the fiscal year ended June 30, 1878. The following table gives quantities of imported tea and coffee retained in the United States for consumption, and the estimated consumption *per capita* of population, during the years 1830, 1840, and from 1850 to 1878, inclusive :—

Year ended—	Tea.		Coffee.	
	Retained for Consumption.	Consumption per head.	Retained for Consumption.	Consumption per head.
	lb.	lb.	lb.	lb.
1830	6,872,091	0·53	38,363,687	3·0
1840	16,882,999	0·99	86,297,761	5·05
1850	28,199,591	1·22	129,791,466	5·55
1851	18,604,774	0·57	143,992,505	6·2
1852	25,387,668	1·03	180,712,687	7·3
1853	19,291,884	0·75	185,999,243	7·3
1854	19,236,113	0·73	150,246,403	5·7
1855	19,768,593	0·72	175,160,441	6·4
1856	18,181,470	0·64	228,626,479	7·9
1857	16,500,285	0·57	216,656,977	7·5
1858	26,766,577	0·97	174,497,161	5·9
1859	23,119,289	0·76	240,820,918	8·1
1860	26,826,928	0·84	182,049,527	5·8
1861	21,916,667	0·66	177,910,452	5·5
1862	23,208,839	0·71	113,013,678	3·4

1864	35,881,022	1·04	127,843,958	3·7
1865	16,849,789	0·49	84,316,045	2·4
1866	[illegible]	1·17	175,794,888	5·0
1867	34,136,216	0·94	172,741,788	4·8
1868	37,655,656	1·02	212,879,267	5·8
1869	[illegible]	1·04	230,814,877	6·1
1870	[illegible]	1·06	253,571,565	6·6
1871	48,972,788	1·19	294,930,949	7·5
1872	34,224,494	0·84	259,785,680	5·9
1873	106,828,570	2·55	401,975,241	9·6
1874	[illegible]	1·27	285,569,219	6·7
1875	[illegible]	1·47	317,017,310	7·2
1876	62,744,429	1·38	338,548,096	7·5
1877	58,941,173	1·28	332,005,687	7·1
1878	[illegible]	1·36	309,956,498	6·5

The consumption of tea and coffee in the United States for each year, from 1830 to 1866, inclusive, is estimated by subtracting the amount exported from the amount imported. For the years 1867 to 1878, inclusive, the amounts of the respective articles entered for consumption at the Custom-houses is taken as the consumption. The population is estimated for years other than the census years 1830, 1840, 1850, 1860, and 1870. The first two years named end September 30, all the others June 30.—*Journal of Applied Science.*

A GOOD HORSE.

WIND, says an old horseman, is the grand secret of a good horse. Good lungs will cover a multitude of faults, while, on the other hand, perfection of shape and form are useless when the wind is out. The chest, therefore, in all cases, should be large and capacious. It may vary somewhat in shape, according to the service to which the horse is to be put. If he is apt to be kept for slow work and heavy drawing, the chest may be nearly circular in form, because this shape is one for strength and bulk to receive and bear up against the pressure of the collar, while at the same time sufficient room is secured for that expansion of the lungs caused by slow, regular work. But if the chest is circular, let it be at the same time deep, or else the lungs may be cramped. A horse with a shallow chest is worthless for any purpose. The rule, then, is : for a draught horse, a circular but deep chest ; but as you pass through the different degrees of speed up to the racer and trotter, the chest will increase in depth, compared to its roundness, until for the highest rate of speed you must take a chest as deep as a greyhound, and at the same time not lacking in strength.

HEALTH OF HORSES.

THE health and comfort of horses have of late years been greatly improved by the better construction of stables. They are made more roomy and lofty, and provided with means of thorough ventilation. In many new stables lofts are done away with, or the floor of the lofts is kept well above the horses' heads, and ample sha fts are introduced to convey away foul air. By perforated bricks and gratings under the mangers and elsewhere round the walls, and also by windows and ventilators, abundance of pure air is secured for the horses; while being introduced in moderate amount and from various directions, it comes without draught. Too much draught is almost an unknown luxury. To secure a constant supply of pure air, horses require more space than they generally enjoy. Even when animals are stabled only at night, a minimum of 1,200 cubic feet should be allowed. In England the newer cavalry barracks give a minimum of 1,509 feet, with a ground area of fully 90 square feet per horse, and the best hunting and carriage horse stables have more room.—*Journal of Chemistry.*

CULTIVATION OF THE AUSTRALIAN BLUE GUM.

WE fear our correspondent "Eucalyptus" gives us credit for more personal knowledge of the subject he refers to than we possess. Our experience has certainly not been much more favourable, if so much so as that of many of our neighbours. Occasionally every one, nearly, of a set of plants put out will grow, but frequently a very small percentage will leave, especially if the plants are allowed to grow big. When they do grow, the trees stand wind better in stiff soil than they do in the loose soil near walks,—that is when exposed to wind. In such positions, there seems nothing for it, but to put *two* large, long stakes slanting inwards to each tree from south-west and north-east. The tree seems naturally to have little tap root, but we have seen one from which the earth had been cut away buttress itself by a tap-root rivalling the trunk in size. The seed seems to grow readily, spread over an unsheltered bed and watered when the weather is dry. Transplanting is the difficult matter, and we should recommend balls of earth and temporary shading. Better go to this expense than lose set after set of plants. But we once published an account of Colonel Beddome's process. It was to cut the bamboo of which estate baskets are made, and which is not more than an inch or two in circumference, into bits about three inches long. Place these pieces endways close together, in thousands ; cover over with forest mould or fine soil and sow your seed. In this way there will be from one to three or four seedlings in each bit of bamboo. When carried out in the bits of bamboo the best plant can be left, the others being removed and utilised immediately or at a subsequent period. Perhaps planters with more experience will give our readers the benefit of their information. A new interest attaches to the cultivation of the Eucalypti as breakwinds or separately, from the fact that the fine straight timber makes excellent sleepers for railway lines where hard wood is desiderated. The trees, many of them, are well grown at eight to ten years old.—*Ceylon Observer.*

STUDIES ON GUANO.

M. CLOUET has been engaged anew in an investigation of the composition of Peruvian guano and some of the mineralogical products found in conjunction with it. Different kinds of guanos vary greatly, as is well-known in their efficacy as manures, the Peruvian variety being especially valuable. The quantity of this latter may be estimated at 738,000,000 metric centners, and it is divided into three different sorts, which were undoubtedly deposited under very different climatic conditions. The first kind is that from the Chincha Islands, now almost exhausted; the second comes from Chanavaya, in the south of the Republic; and the third variety is obtained from the Guanape Islands, towards the north of the country. The average composition of the three sorts is as follows:—

	Chincha Islands. Per cent.	Chanavaya. Per cent.	Guanape Islands. Per cent.
Uric acid	12·000 ...	15·500 ...	0·900
Oxalic acid	4·464 ...	3·609 ...	8·810
Phosphoric acid ...	12·100 ...	19·030 ...	12·560
Carbonic acid... ...	0·600 ...	— ...	8·700
Sulphuric acid ...	2·050 ...	1,960 ...	2·000
Chlorine	2·988 ...	1·240 ...	1·500
Lime	18·950 ...	16·020 ...	14·640
Magnesia	0·520 ...	1·100 ...	0·400
Potash	2·100 ...	2·250 ...	2·200
Soda	0·000 ...	1·200 ...	1·100
Ammonia	11·100 ...	8·500 ...	9·100
Silicic acid	1·900 ...	2·000 ...	1·180
Hygroscopic water ...	10·500 ...	5·200 ...	20·000
Undetermined organic substances	24·840 ...	22·400 ...	26·990
Total nitrogen	14·47	12·18	10·29

Hence it appears that the guano from the driest regions is richest in uric acid, which in the Guanape variety is washed out by the rains, while, on the other hand, the proportion of carbonate of ammonia in it is largely increased.—*Country Gentleman's Magazine.*

SELF-DEFENCE AMONG PLANTS.

ONE of the means of self-defence among plants, says Dr. Francis Darwin, in a recent lecture, is the presence of poisonous alkaloids. Thus ruminants will not eat such plants as nightshade (belladonna) monks hood (aconite), hellebore, thorn apple (stramonium), paeony, veratrum, and hemlock (conium). Many plants are protected by their poisonous milky juices, as the spurges (euphorbia) poppy, celandine, and others. In the strychnos nux vomica, the poisonous alkaloid strychnia is contained in the seeds, its whole object being to prevent them and the young plants contained in them from being injured, the fleshy parts of the fruit being quite harmless and eaten by the natives. This eatable part surrounding the seeds entices birds to swallow them, that they may be distributed after, and by passing through the animals' bodies. Bitter almonds are comparatively safe from the attacks of mice, whereas sweet almonds are much injured by them. In addition to an almost endless series of poisonous plants, there are those which contain essential oils having a pungent aromatic odour or taste. Thus the fennel, aniseed caraway, and others have otherwise unprotected seeds, which are safe from the attack of birds on this account. In Brazil the lime alone of all the orange tribe is distasteful to the leaf-cutting ants probably owing to an oil similar to that which gives the strong taste and odour to orange peel; and this fact has decided the fate of the tree, for it is the only species of the tribe which has been able to establish itself beyond the limit of cultivation, the orange, citron, &c., growing only where protected by man. Turpentine in fir leaves serves as a protection against cattle. The aromatic flavour of mint is a defence against browsing animals, and as it is frequented by a large number of insects, it affords an analogy to the nettles and thorns, which are resorted to by butterflies and birds to rear their young. Flowers are usually more acrid than the plants which bear them, and are thus protected from destruction by browsing animals and other foes, by being uneatable. Caterpillars will die of hunger rather than eat the flowers of the plants whose leaves form their natural food.—*Australasian.*

THE IVORY NUT PALM.

A WRITER, in a recent number of *Science Gossip* states that in 1843, Mr. William Purdie was despatched to New Granada to collect plants for the Royal gardens, Kew. He was specially instructed to find a few special plants, one of which was the ivory nut palm. In his account of this Mr. Purdie says:—"In a journey of 600 miles from Santa Martha to Ocana, in new Granada at the village of Sámana, seventeen leagues from hence, and near the great river Magdalena, I entered the mountains, and saw for the first time the ivory nut palm (Phytelephas macrocarpa), called *Tagua* by the natives. The habit of this palm is to have little or no stem, what there is is decumbent; it is not a robust tree. Old plants have from 15 to 20 primate leaves, which when fully grown measure nearly 20ft. in length, of a delicate green colour, very graceful, and similar to those of the date palm. The male and female flowers are borne on separate plants. The male flower are produced generally in six clusters from the bases of the leaves and on short footstocks. The clusters are compact and form a nearly globose head, which, on account of the style-like projections resembling the rigid hair of a negro, is not inaptly called *Cabeza del negro* (negro's head). These heads lie close to the ground, each cluster containing four or five seeds. The seed contains, at first a clear insipid liquid, which afterwards becomes milky and sweet, and ultimately hardens and becomes the 'vegetable ivory, of commerce. Each of these nuts is about the size of a green walnut, and is covered with a yellow, sweet, oily pulp, which is collected and sold under the name of *Pepo del Tagua.* A spoonful of the latter with a little sugar and water makes the celebrated *Chiche de Tagua*, said to be the most delicious beverage of the country."

KEEPING UP FLESH.

THE bare pastures (says an American contemporary) will suggest the absolute necessity of feeding to keep stock growing. Young stock suffer more than mature stock from falling off in flesh in the fall, and for the reason that, besides the actual loss of flesh from insufficient food, young stock receive a check which they do not subsequently recover. In this connection the question of shelter comes in as an important integer. No animal should be left exposed to chilling storms in late autumn or winter. It is simply a question of the conservation of force. If an animal, whether a horse, a steer, a hog, or sheep, or young animal loses flesh, it loses force. To regain this, not only must the feed be supplied to keep up the natural waste, but the flesh lost must also again be put on. Thus all the animal waste formerly supplied in originally gaining the same amount of flesh is a dead loss, but the time lost in losing and again gaining this flesh must again be taken into account. Thus the wise farmer not only feeds early and well, but he also shelters early and well, knowing that the loss of heat means loss of flesh, and that loss of flesh means loss of profits. In all this the stock raiser, of course, is guided somewhat by the relative cost of shelter and the cheapness of food; nevertheless we always find that those who give the best shelter have the best stock, and for the simple reason that warmth conserves the natural heat in animals as well as man.

COVERED YARDS FOR YOUNG STOCK.

THE question of covered yards for young stock is one that has been much debated. Those who are in favour of them have at least two cogent arguments to support their views—the additional shelter afforded to the cattle, saving thereby a given quantity of food; and the economy of litter, much of which is always trodden to waste, or next to waste, in open yards. On the other hand, some writers contend that open yards are conducive to the health and hardiness of the animals; fresh air, and even exposure to the elements, being necessary to give them the desired vigour of constitution. It is true enough that young animals may easily be injured by being kept under cover too much, but we fail to see any advantage in exposing them to the storms and blasts of winter. Fresh air is necessary to them, and so is exercise, but it is a simple matter enough to arrange that they shall have plenty of both in connection with covered yards. The mistake made by those who on these grounds condemn covered yards lies in assuming that when once put in the yards the cattle are not allowed out of them during the winter. In this matter we may admit the teaching of instinct in the animals. If young stock have a building, a shed, or a covered yard into which they can retire when they choose, we find they always do retire into it in bad weather, and that they require little or no teaching to do so. So with covered yards it is a simple matter, which suggests itself to any one, to allow the animals to go out in fine weather and to come in in foul; they will do both these things of their own accord, if they are allowed.—*From 'Dairy Farming,' by Professor Sheldon.*

THE WAY TO HANDLE SHEEP.

THERE is a right way and a wrong way, a hard way and an easy way, an awkward way and a skilled way, to catch and handle sheep. A great many men will catch the sheep by the wool on the back with both hands, and lift the animal clear from the ground by the wool only. Barbarous! Let some great giant grasp you by the hair of your head, and lift you from the ground by the hair only! Would you not struggle and squirm worse than the mute sheep does when lifted by the wool? And would there not be a complaint of a sore head for a week or two? If

you do not believe it, try the experiment. We have slaughtered a great many sheep in years past, and when removing the pelts of such sheep as had been handled by the wool, we never failed to observe that beneath the skin, wherever the animal had been caught by the wool, blood had settled. In many instances, the skin had been separated from the body so that inflamation had become apparent. We have known proprietors of sheep to be so strict in regard to handling them, that they would order a helper from the premises if he were to catch a sheep by the wool on any part of the body. Some owners of sheep direct their helpers thus:—'When about to catch a sheep, move carefully toward the one to be taken, until you are sufficiently near to spring quickly and seize the beast by the neck with both hands; then pass one hand around the body, grasp the brisket, and lift the sheep clear from the ground. The wool must not be pulled. If the sheep is a heavy one, let one hand and wrist be put around the neck and the arm pressed against the leg.' We have always handled sheep in the way alluded to. We never grasp the wool. Others seize the sheep by a hind leg, then throw one arm around the body and take hold of the brisket with one hand. But ewes with lambs should never be caught by the hind legs, unless they are handled with extreme care. When sheep are handled roughly, especially if their wool is pulled, the small bruises and injuries will render them more wild and more difficult to handle.—*Drover's Price Current.*

CAN LEAVES ABSORB WATER?

SOME short time since we had occasion to allude to the experiments of the Rev. George Henslow, from which it appeared, contrary to the opinions expressed by Duchartre and others, that leaves do absorb water. We have now before us, in the *Bulletin* of the Botanical Society of France, the record of some further experiments on this subject by M. Mer, and which confirm Mr. Henslow's experiments. M. Mer's conclusions are as follow:—

1. Leaves can absorb water either when they are entirely submerged after having lost their turgidity, or when liquid is in contact with a portion of their surface only, the remaining portion being subject to transpiration.
2. Absorption is more active on the lower surface than on the upper face, more active also in leaves with thin cuticle than with those with a thicker epidermis. In the former case absorption occurs to such an extent as to prevent the drying up of the internodes and leaves not immersed in the water, when these organs receive water from no other source; it is nevertheless sufficient to preserve the turgidity of the roots. In the second case this absorption is not strong enough to restore the weight the plants had before being withered.
3. The absorption is not local merely, as it induces turgidity in neighbouring parts. Moreover all the tissues of a plant are more or less continuous (*solidaires*) with reference to water.
4. The leaves do not absorb water when (*a*) they are still turgid, unless there are adjacent organs transpiring rapidly; nor (*b*) when they have at their disposition tissues rich in water, and from which by preference they derive their supplies of water when slightly withered.—*Gardener's Chronicle.*

AGRICULTURE IN THE UNITED KINGDOM.

AT a time when agriculture is in so depressed a condition, it is of interest to inquire what has been the tendency observable amongst the farmers of the United Kingdom of late years. Has the area under cultivation increased, diminished, or remained stationary? And how have the cultivators directed their efforts in order to meet the trials that have come upon them? In the Agricultural Returns which have just been issued by the Statistical Department of the Board of Trade, we are furnished with the means of answering these very important questions. It is due to Mr. Giffen to say that since he became head of the department these returns have been much improved. They are collected earlier than they used to be, a summary of them is promptly delivered to the press, and the complete tables, with accompanying comments, are given to the world as soon as the harvest itself is got in—at present, indeed, before it. The information contained in them is thus made available while it is really useful. Moreover, the amount of information has been largely increased, and it is of a kind which enables us to institute instructive comparisons without having to consult other publications. The agricultural statistics for the colonies and foreign countries, it is true, have been omitted, as we think with advantage; but in their place we get an expansion of the home tables giving the results of the previous nine years, and, in addition, we have most valuable information respecting prices, imports, and other matters bearing on the subject in hand. By the aid of these we can frame answers to the questions propounded above. It may be well, however, before we proceed further, to make somewhat more distinct the nature of the problem with which we propose to deal.

In 1859 the population of the United Kingdom was, in round numbers about 29½ millions; last year it was about 33¾ millions; the increase, therefore, was 4¼ millions, or 15½ per cent. But the value of the imports of food of all kinds rose in the same interval from 21,359,000*l.* to 95,996,000*l.*—that is to say, was almost quadrupled. The imports of food thus increased out of all proportion more rapidly than the mouths that consumed it. This will appear still more clearly when we say that these imports in 1859 amounted to no more than 17*s.* for each man, woman, and child in the kingdom, and that last year they were as much as £2 16*s.* 10*d.* for each. In other words, when we have made full allowance for the growth of the population, the imports of food have nearly trebled in value in twenty years. It may perhaps be said that a large part of them consisted of articles not produced in this country, such as tea, coffee, sugar, rice, wine, brandy, fruits, and so on. Let us, then, take the headings separately as given in the volume before us, and we find that the value of the live cattle, sheep, and pigs imported has risen from 1,684,000*l.* to 7,458,000*l.*; of the meat, butter, cheese, eggs, and potatos, from 4,680,000*l.* to 29,478,000*l.*; and of the corn, grain, flour, from 18,044,000*l.* to 59,664,000*l.* We omit in every instance the odd hundreds; but the omission does not materially affect the result, which manifestly is that the land of this country has not produced enough for the wants of it population. If now, with these facts before us—that the land of the country has not produced enough to satisfy the wants of the population, and consequently that in twenty years our food imports have been almost trebled—we inquire what has been the course of prices, we get a very strange reply. In 1859 the *Gazette* average price of wheat was 43*s.* 9*d.*; last year it was 46*s.* 5*d.* The year of the Italian war, 1859, was perhaps the finest within the memory of the present generation, and therefore was highly favourable to the growth of wheat. Last year was very unfavourable, and the harvest was bad. Yet, in spite of this, and in spite of the further fact that last year there were five and a quarter million additional mouths to fill, the rise of price was no more than 2*s.* 8*d.*, a trifle so small as not to be worthy of notice. Indeed, between 1859 and 1876 there was a difference of 9*s.* 6*d.* The rise in barley in the twenty years has been from 33*s.* 6*d.* to 40*s.* 2*d.*, but in 1876 the price was as low as 35*s.* 2*d.*; in oats the rise has been from 23*s.* 2*d.* to 24*s.* 4*d.* Practically, then, there has been no advance in the price of corn. In wool there has been a very great fall. In 1865 English fleeces fetched as much as 2*s.* per lb.; last year they were as low as 1*s.* 3½*d.* This is a decline of over one-third. In pigs, again, the price has been stationery. And even as regards butchers' meat the rise in no case amounts to 50 per cent., and often is not above 20 per cent. And, if the prices of the present moment were taken instead of those of last year, the advance would be found to be still less. It is not to be forgotten, however, that in 1859 the effect of the gold discoveries, and of the great outburst of trade activity that followed the repeal of the Corn-laws and the application of steam to locomotion, had already begun to tell upon prices. But this does not affect the point to which we wish to direct attention—namely, the vast augmentation of our food imports simultaneously with; small advance, or no advance at all in prices, and the effect of this combination of circumstances upon agriculture in the United Kingdom. What, then, has been this effect?

In one respect it has been different from what might have been expected from the foregoing' facts. One would be inclined to infer that foreign competition is overbearing home agriculture, and to look in consequence for a diminution of the area of land under cultivation But, on the contrary, there is a steady increase. In 1870, the earliest year for which in the publication we are treating of the statistics on this subject are given, the total area in cultivation in England, Wales, and Scotland was 30,407,579 acres; last year it had risen to 31,975,784, an addition of 1,568,205 acres, or about 5 per cent. Some of this increase, no doubt, is merely apparent. Greater accuracy in the returns swells the total acreage. But there is also a real extension of cultivation by the reclamation of bog and moorland and waste mountain sides. This reclamation is going on even in the present year, when we hear so much of agricultural distress, showing that the wealth of the country is growing even in the worst times of depression, and that a fair return is made for the cares of the skilful husbandman. But while the total area under cultivation is thus receiving annual increments, the acreage under tillage is constantly diminishing. Thus the area under corn has fallen from 9,548,000 acres, omitting the odd hundreds, to 8,935,000 acres, under grass crops from 3,586,000 acres to 3,554,000 acres; under clover from 4,504,000 acres to 4,478,000 acres. It will be seen that the falling of is mainly in the breadth of land under corn; and in this category it is principally in the wheat area, which has decreased from 3,590,000 acres to 2,890,000 or over 600,000 acres. In oats again there is a diminution of 107,000 acres, in potatos of 66,000 acres; and in turnips of nearly 200,000 acres. In the area under barley, on the contrary, there is an increase of 296,000 acres. It is in the acreage laid down in permanent pasture that the whole augmentation is found; but the increase in cattle is by no means proportionate with this augmentation. There is, in fact, a decrease in the number of both sheep and pigs. And in cattle the increase does not exceed 428,000 head. The change that is being effected in our system of farming can hardly, therefore, be considered satisfactory. The seasons since 1870 have been very unpropitious, and perhaps, therefore, it was inevitable that the growing of wheat should be more and more restricted. The cheapness and the highly nutritive quality of maize, too, make it a formidable competitor of oats. But that tillage generally should fall into disfavour is not so easy to understand. With more of the country laid down in permanent pasture we have fewer sheep and not very many more cattle, while foreign meat is underselling home-fed in our own markets. It seems to follow that the course pursued by our farmers is a mistaken one, and that the

would do better if they were to till more. It is certain at any rate, that our agriculturists have not kept pace with the times. It would appear that the present depression is rousing them to exertion, and that in many instances they are discovering ways of making money which had previously been neglected. In the current year, for example, there is a considerable increase in the acreage under orchards, and there is also an extension of market-gardening. The very high price of fruit proves that there is room for enterprise at home in supplying an increasing want, while the growth of our urban population provides a perennial and increasing demand for fresh vegetables. There is no reason but routine why farmers in the neighbourhood of large towns should not devote a part of their holdings to the growing of these. In farming, as in every other business the pinch of hard times seems to be needed to make men put forth all their energies and give attention to small gains and minute economies. If the present depression compels our farmers to do this, they will find means of meeting the foreign competition which is now too much for them.

Hitherto, however, it must be confessed that the improvement in the condition of the people of England, the rise in the standard of living amongst them, and the consequent great demand that has arisen for food products of all kinds, have stimulated only agriculture abroad, not at home. For example, it appears that the area under wheat in Australia has doubled within the last eight years, and that it now exceeds 2½ million acres. In the United States this year the breadth of land under wheat exceeds the enormous total of 32⅔ million acres, or more than ten times the breadth under wheat in the United Kingdom. The yield per acre, however, is very small, and the whole crop, therefore, will be very much less than those figures would lead one at first sight to expect. Yet these figures, after every allowance is made, afford eloquent proof of what we have said, that it is distant countries, not our own, which have been stimulated to supply the growing demand in these islands for the necessaries of life. Vast, however, as is the area under wheat, that under maize is still vaster, it is over 58 million acres. These figures bring out very clearly how different the tendency is at home from what it is in those newer countries. Here there is a diminution of tillage continued year after year; there we see a rapid extension. The seasons since 1870 have been exceptionally bad at home, and have accelerated the movement; but it had set in long before, and the disposition undoubtedly is to regard it as one that must go on. Probably it is impossible to compete with these new countries in the cultivation of wheat, but we clearly have an advantage in the cultivation of barley, and, we venture to think, in other things beside. If the same skill, enterprise, and capital were applied to the soil which are applied to trade, we believe it would be found that agriculture in the United Kingdom may still be a profitable business. But our object now is not so much to insist upon this point as to bring out the effect produced on British agriculture by the influences acting upon it.—*Saturday Review.*

THE BIGGEST WHEAT FARM IN AMERICA.

THE United States, although famous for great business undertakings, have not many large wheat-growing farms. Throughout the Eastern, Middle, and even the North-Western States the ordinary grain farmer seldom possesses more than 200 acres. But here at Casselton, in Dakota Territory, in the valley of the Red River, is a striking exception—a farm of 75,000 acres held by Mr. Oliver Dalrymple. Four years ago this enormous farm was a portion of the far-reaching prairie wilderness. No evidences of human life were visible. Prairie fowls, snipe, jack rabbits, the prairie squirrel or gopher were the inhabitants; while wild ducks and geese congregated in creeks or marshy spots. A few years previously buffaloes and badgers were common, and on the untilled prairie their whitened bones lie thickly strewed. Some of the directors of the Northern Pacific Railway had acquired these lands and wisely appointed Mr. Oliver Dalrymple their manager, with a half-share in the concern. Mr. Dalrymple brought to his serious task a goodly experience, acquired in successfully farming 6,000 acres at Lake Elmo, near St. Paul, Minnesota.

On Friday, the 26th of September, the members of the Royal Commission; Messrs. Read and Pell, your Commissioner, and a party under the guidance of Mr. James H. Drake, Assistant Manager of the St. Paul and Sioux City Railway Company, were most hospitably received by Mr. Dalrymple; were driven for miles over this vast prairie farm; examined its dark, triable; alluvial soil, perfectly free from stones, varying from 12in. to 20in. deep, resting upon an argillaceous clay rich in vegetable remains; gathered information as to the cost of wheat production, and speculated on the permanence of continuous wheat-growing. The arrangements of this great farm are well considered and systematically and effectually carried out. Minor details receive more attention than on most farms of 100 acres; time and labour are everywhere economised. On one of the sub-divisions of the property telephonic communication, at a cost of only $300, is established between the superintendent's office and that of his foreman; and this rapid and direct system of control is being extended throughout the whole estate. Substantial and economical wooden buildings have been erected at suitable points, consisting of houses for superintendents, sleeping and dining rooms for the men, stables, granaries, and sheds for the storing of the numerous and valuable machinery and implements, with blacksmiths' and carpenters' shops. Handy to the several buildings, wells varying from 50ft. to 80ft., have been dug into the sand and gravel bed which underlies the clay; On one farm avenues of trees are planted out. Amid such modern equipments and good cultivation it is difficult to realise that this busy profitable settlement was five years ago lonely, barren prairie.

This Dalrymple property cost from 40c. to $5 per acre. There are no federal taxes; rates, mostly for school purposes, amount to 10c. per acre. The estate is partitioned into divisions of 5,000 acres, each under the management of a divisional superintendent, who has under him two foremen, one of whom, on horseback, accompanies his 15 or 20 teams to work, sees to the ploughing or drilling, observes and reports as to the behaviour of the men, the condition of the animals, and the efficiency of the machinery. Each division has two or more sets of buildings, and in connexion with the principal homestead of each farm are the quarters for the men—large wooden barrack rooms, sometimes over the stables, comfortably warmed with stoves, where 50 men sleep in busy times two in a bed. Hard by are the kitchens, each with the capacity to provide for the wants of 100 men, presided over by the cook and his mate, who, on requisition through the foreman, draw supplies from the stores—flour for bread, puddings, and cakes, beef which costs fresh fully 8*d.* per pound, pork, bacon, cheese, and butter, and coffee, and other good things. But the stores, liberally provided with necessaries and luxuries, including some of the best butter and coffee we ever tasted, wisely dispense neither beer nor spirits. Three hot meals a day are provided, before 6, at noon, and at 7; meat, bread, puddings, cakes, tea and coffee are supplied without stint. All payments are made by the book-keeper on vouchers signed by the foreman. Men can draw their money as they please. Some take it weekly; a few spend it at the beer saloons at Casselton; others, more provident, allow it to run on for weeks, or even for half a year. The rate of wages varies with the season. With board during the spring $18 a month (18*s.* a week) is given; during harvest wages advance to $2·25c. a day; during the thrashing season the rate is reduced to $2; during the autumn months the pay is $2·5. No piecework is adopted, but so thorough is the superintendence that full work is obtained from both man and beast. During harvest and thrashing, which is done out of the field, as many as 600 men are frequently employed. Even with this great accession of labourers, work proceeds systematically and harmoniously. No rows occur; brawling and fighting are extremely rare, but when they do occur it unfortunately is usually on Sunday. Dismissal for insubordination is scarcely known. Men injured or sick from causes beyond their own control are nursed and have medical attendance gratutiously. Extra men in harvest and during thrashing only receive pay for the hours they labour. So soon as frost prevents ploughing, the whole of the men on the farms are dismissed, with the exception of the divisional manager and about ten men, who each look after about 40 mules or horses, feed and water them, and turn them into a yard for a quarter of an hour's exercise night and morning. Hard as such wholesale dismissal would be in Great Britain, it is no hardship here, for these men readily find lumberwork in the forests. It is obviously an enormous boon thus to get rid of men whom the farmer cannot profitably employ during the five winter months. Many an English wheat grower would gladly practise this retrenchment and send most of his staff to other vocations during the short days and bad weather of mid-winter. Twenty thousand acres are already under cultivation; 5,000 acres are broken up annually. The uncultivated portions are chiefly used in growing prairie hay and grazing the milch cows. Four hundred mules or horses are at present daily engaged ploughing the stubbles, or back-setting or cross-cutting the land broken up from prairies during the early summer months. The sod of ages is already disintegrated, the prairie grass, previously, cut short by the mowing machine, is rotted. The stubbles are left of about the same length as they are in England; but since the straw is burnt it would save expense, both in reaping and thrashing, to leave a longer stubble and burn this and any weeds among it before the ploughs went to work. In one field we come upon nine double-sulkey ploughs; the ground being hard owing to a month's dry weather, four mules are allotted to each. The driver mounts comfortably, as on a reaping machine, guiding his four-in-hand with reins. Instead of a coulter, these ploughs made by John Deer, Illinois, and costing $60, have a cutting wheel. The working parts are of steel; the shares are sharpened every third or fourth day. Each of the two ploughs turns a furrow 15in. wide by 5in. deep. In another field a dozen mule teams are similarly employed. Two and-a-half acres are at present turned over by each team daily; but when the ground is softer fully three acres are overtaken. The teams walk 17 to 20 miles daily, turn out at 6, are in the stable and fed for an hour at noon, and have four to five hours' work in the afternoon. The fields are conveniently laid out in squares of 100 acres. Some are fenced with oak posts and two strands of barbed steel wire, which keeps back cattle and horses, but not sheep and pigs, and has the disadvantage of lacerating any animal coming forcibly into contact with it. To prevent idly walking several miles to work, the teams going and returning, invariably plough along the intervening fields, the twelve teams each time they go out or return contributing a broad strip of nearly 30ft. of ploughing.

The breaking up of the level prairie is neither tedious nor costly. No stones or tree roots cause breakage or delay. With the single hand ploughs and a pair of horses, or three abreast if the ground is very hard, a stout furrow, usually measuring 12in. by 4in., is turned. An acre and-a-half is easily overtaken in the May or June day or ten hours. Mr. Dalrymple estimates that the breaking up, allowing for wear and tear of plough and sharpening of the steel shares, which should last two seasons, costs him fully two and-a-half dollars. The stubble and cross-ploughing are computed to cost $1·75c. Even in this newly-settled country, small farmers and others can be hired to do the ploughing, furnishing a man and pair of good horses

at the cost of 12s. daily, and doing regularly their 1½ acre in a workman-like manner.

Mr. Dalrymple and Mr. Dutton, one of his intelligent and able divisional superintendents, both prefer mules to horses on account of their hardiness endurance, equable temperament, and freedom from disease. With about an equal proportion of mules and horses they have in four years used up 16 horses, but the whole of the mules are still serviceable, excepting one, which was accidentally injured. The mules are bought chiefly at St. Louis at five or six years old; they are 16½ to 17 hands, weigh 1,100lb. to 1,200lb; are well broken, steady workers, good-tempered, and quiet, and cost on an average $140 (£28), while the transit of 1,000 miles from St. Louis home puts about $10 (40s.) more on their price. Mules and horses do not differ much in value, and are managed and fed alike. They are housed in good lofty stables, accommodating about 50, standing in pairs in 9ft. stalls. Racks and mangers are used as at home. They are tied by halters or head-stalls. The light harness, used indifferently for plough and wagon, costs $28 for each animal, and is expected to last ten years. The feeding, carefully attended to by the stable "boss," consists of 12 quarts daily of mixed home-grown oats and barley, and 15lb. to 20lb. of prairie hay. During winter, the amount of corn is of course reduced, and this five months' rest and some days' lighter labour between seasons accounts for the good looks and condition of the teams and their standing satisfactorily at busy times, 11 hours work daily.

Towards the end of March the working staff are again got together. The lumbering is finished up, and men are ready for farm work. A few of the hands of former seasons return. The gang foremen, selected for intelligence and promptitude, are appointed. The whole of the land intended for crop has been ploughed in autumn; the newly broken, as indicated, has had a second furrow, which keeps down weeds and insures more certainty of result. So soon as the frost has left the first six inches of soil, which is generally by April 1, the seeding of the wheat commences. Scotch Fife, a good, hard, thinned-skinned red variety, is used. The seed is selected from the newly broken-up land; if any cockle or other weeds are observable, they are carefully winnowed out. No dressing or picking is adopted. During autumn or winter, in 1½ bushel lots, the seed for each acre is bagged up. Whenever the weather permits seeding commences. The seed is distributed by broadcast machines, 100 being at work daily for three weeks. Two hundred sets of harrows complete the operation, two or three turns being required, and Mr. Dalrymple jocosely states that he orders it "to be well done, and then give one turn more." Four harrows, united by chains, work in a set, cover 30ft., and are drawn by four mules. In each harrow are 72 round teeth; the set costs 14 to 15 dollars. Immediately after the wheat seeding, the oats and barley grown for horse provender are put in.

No horse or hand hoeing, no weeding, or any further expenses are incurred until harvest. Seasonable showers usually occur during June and July; heavy dews restore part of the moisture removed during the warm noontide. For four years the seasons have been propitious. The drought during last July occasioned, however, considerable apprehension. Prayers for rain were offered in the churches, while English farmers were imploring fine weather. Another week of scorching drought would have shrivelled up the soft, milky ears; but the much longed-for rain came seasonably. Drought is probably the chief cause of uncertainty in the American wheat yield. Hail-storms and tornadoes, abounding further south, are unknown here. No wire-worm, weevil, or fly interferes with Mr. Dalrymple's crops; mice and rats have not yet made their home in Dakota; sparrows, larks, and rooks are equally rare. Grasshoppers did some injury in 1876, probably diminishing the yield by three bushels an acre; but Mr. Dalrymple considers that he is too far north to suffer much from the hoppers, and believes that they cannot do much damage on cultivated land, although why such marauders should spare the cultivated crops is not very evident.

Harvest begins about August 1, usually amid fine, settled Californian weather. About 800 extra men are engaged. One hundred and fifteen automatic self-bindings harvesters are busily at work; 100 of these are Walter Wood's, the remainder M'Cormick's. Both are reported to do their work admirably; no objection is found to the wire binding. The grain is shocked, and cutting is overtaken in 12 days No time or outlay is expended in stacking. The 21 steam-thrashing machines made by the Buffalo Company, and costing $600, with thrasher, winnower and straw-elevator in one, are placed at convenient points throughout the fields. Ten wagons, each with a pair of horses or mules, bring up the shocks and carry off the thrashed corn in three-bushel bags an average distance of two miles to the railway cars. A gang of 25 men keep wagons and thrashing machines steadily going, and deliver at the station 1,000 bushels of wheat daily. Each day the thrasher and engine which is partially self-propelling and costs $800, is moved, so as to shorten haulage of the sheaves. Every busy day, 50 railway cars, each containing, 400 bushels, are loaded, and stand ready for despatch, usually to Duluth 264 miles distant, on the western corner of Lake Superior.

The crop of the present year Mr. Dalrymple states to be much the same as that of former seasons. It averages 20 bushels an acre of 60lb. to the bushel. The natural weight is 59lb. to the bushel. As usual the produce of the newly broken up land is best. The quality is fully as good as that of 1878. When run once through the winnower at Duluth, it will be graded No. 1 hard. Mr. Dalrymple usually sells as fast as he can deliver, but this year, holding for the rise, he has still the chief portion of his crop warehoused at Duluth. The oats are reported to yield 50 bushels to the acre and 33lb. to the bushel; last year 60 bushels were produced. The barley has not done particularly well this year; but generally runs 40 bushels. On each farm a few potatoes, cabbages, swedes, and other vegetables are grown for home use and for the cows which are kept to supply dairy produce; but wheat-growing is the great business of this great farm.

Now comes the important question of the cost of production. Mr. Dalrymple furnishes the following figures:—Land valued at $12 per acre, interest thereon at 6 per cent., 72c.; taxes and rates, 10c.; buildings, machinery, and teams, valued at $10, interest at 10 per cent., 100c.; ploughing, $3, seed, $1 50c.; harvesting and threshing, $3; total, $8 42c.

Mr. Dalrymple thus produces an acre of wheat for less than $8½ (34s.) per acre; indeed, he asserts that hitherto the actual cost has not reached $8, excepting in the case of the first year's crop which the extra expenses of breaking up and two ploughings advanced to $11. For four years his acreable yield has averaged 20 bushels, each of which on the basis of the above calculation, would cost 42c., or 1s. 9d. On his own and other suitable wheat-growing farms in favourable seasons, Mr. Dalrymple declares that the crop does not cost more than 35c. per bushel. Sold, as it readily can be at the railway station at Casselton, at 75c. to 80, a very handsome profit is obtainable. It approaches the Dutchman's 1 per cent., which on investigation proved to be a cent. per cent. return.

But now important alike to producer and consumer, comes the question. Will these crops and profits be permanent? No symptoms of deterioration are yet apparent. The land is clean; neither twitch, thistles, nor docks appear. The chief weeds are wild cotton, barn grass, a sorrel with a yellow flower, and the Michaelmas daisies. The manure made from the stables lies about in heaps which it is not yet thought worthwhile to apply. Excepting the small quantity of straw used for littering the animals, the whole produce of the 20,000 acres is burnt The spots on which these heaps burn show no obvious difference from the rest of the field, indicating that the unassisted soil still contains phosphates and potash sufficient to grow full crops. How long the continuous corn-growing can be profitably continued, is somewhat difficult to foretell. On similarly good land in various parts of the country fields are pointed out from which, without any restorative treatment, 20 consecutive crops of wheat have been reaped, and neither quantity nor quality as yet undergoes obvious diminution. Mr. Dalrymple is, however, too prudent a farmer to draw too long or deeply on the resources of his land. By ploughing year by year an inch deeper, he brings up fresh plant foot; by growing, at intervals probably of four years, as he purposes doing, a crop of clover, rolling it down and ploughing it in, he intends cheaply to maintain fertility. By these means and by selection and change of seed, as well as by an occasional crop of oats or barley, Mr. Dalrymple's superior management will doubtless secure a continuance of good crops for many years.—*Mail.*

THE APPLICATION OF NITRATE OF SODA TO CEREAL CROPS.

MR. HORATIO CHANCELLOR, Chessington, Surrey, writing the other day to *Bell's Weekly Messenger*, says :—

I have just threshed my experimental plots for this year. As some few of your readers may like to know what nitrate of soda has to say for itself this remarkable season, I send you the results. I have always found this valuable stimulant make the best return in a moderately dry summer. The following statements will show, however, that it possesses to no small degree the power of rescuing vegetation from drowning. This is especially to be noticed in the barley series.

The proportion of grain to straw is small throughout—a prevailing feature of this year's harvest. I may say that locally the yield of grain was very considerably diminished by the terrific hailstorm which we experienced here in full force in the beginning of August. The wheat ears in some fields were fairly cut asunder, and generally so severely bruised and damaged as to suffer more than ordinarily from the continuous rains which followed upon the hail. The barley was also literally beheaded to a large extent especially in the heavily nitrated plots.

The series of trials given below have been carried out with a twofold object.

1st. As in previous trials, to find out to what extent nitrate of soda can be applied with safety and profit by dressing up to as near 'danger point' as possible.

2nd. As a new feature, to find out the advantage (if any) of applying the same quantities in small doses at intervals of two or three weeks.

The produce grown on plots upon which the nitrate has been applied in two or three distinct doses has not been threshed, only the gross weight of sheaves being given. The monetary return is calculated on the assumption that the relative proportions of grain and straw are the same. The yield of grain per acre is given in bushels of natural weight (head and tail corn together, and valued at a low figure accordingly. The yield of straw is given in market trusses of 36lbs., valued at present prices. The deficit from gross weight of sheaves is made up by short straw, chaff, &c.,

averaging six to eight per cent. of the whole produce. No estimate is made of this, however, in the returns below :—

WHEAT.—The enormous weight of straw grown per acre is the chief feature of the wheat plots—an amount so great as to lead me at first to doubt the accuracy of the returns. Testing, however, other portions of the same field, I found that they fairly agreed. I have known the same apparent bulk of straw produce little over half the weight. The fact of cutting the crop in a partially green state and the sunless character of the season have both helped, no doubt, to lead to this. On the other hand, the natural weight of grain is the lowest I have ever known, being only 57lbs. per bushel. The weight varies but little on the different plots—perhaps ½ lb. in favour of the undressed. The light weight of grain is owing jointly to a want of condition and large percentage of tail corn. By reducing the bulk one fourth a fair sample of 61lb. is obtained. The returns given above as resulting from the use of nitrate of soda are fairly satisfactory for this season. Had the wheat experimented upon been of a stiffer-strawed variety, such as the square-head, the proportion of grain would have been much larger. Plots of these two varieties tested side by side in the same field proved this, the squarehead being quite erect at harvest, while the rough chaff was very much laid. The fact of the undressed plot making such a fair return this unfavourable season, proves that the land was in a sufficiently high condition to produce a good crop without any top-dressing whatever. Indeed my fear before thrashing was that I should find for once that the heavily nitrated plots revealed a loss. The above statement proves, however, such not to have been the case.

BARLEY.—The miserable yield of barley is but another melancholy characteristic of this harvest. On the heavy lands very generally the crop has proved a failure, both in quantity and quality. There was a very fine and vigorous plant growing on the field from which these experimental plots were taken up till the end of May ; but, under the influence of incessant rains and cold nights, it utterly succumbed early in June. The nitrate was applied during June, and an almost magical effect was produced in a few days. The land being in a fair condition, a quick-acting stimulant was only wanted to restore a healthy appetite to the plant. The low temperature of the soil and want of sun rendering the crop hopelessly prostrate, nitrate of soda was here invaluble. The poor return of grain, after all on the most highly-dressed plots is largely owing to the severe hailstorm previously mentioned, the increase of straw being very great, the returns varying from 1360 to 5560lb. per acre. The natural weight per bushel also varies considerably from 50lb. on the undressed to 53½lb. on the highly-nitrated plots. The difference in value was estimated by an experienced maltster at 10s. per quarter. In the above statements values are placed at 36s, 42s, 44s. The weight could be easily made up to 55 or 56 lb. per bushel by screening, &c.

OATS.—Only a moderate yield, but of superior quality. The natural weight per bushel differs but little ; 37 to 37½lb. in favour of the undressed plot could be made up to 40lb. The heavily-dressed plots were somewhat broken down by the hail and rains. The proportion of grain to straw would have been higher if the crop had been upstanding.

GENERAL.—Taking a general survey of these experimental plots, it is certainly no easy task to arrive at any very definite conclusions. It will be seen that throughout the whole series the plots receiving the superabundant dose of 3cwt. nitrate mixed with 3cwt. common salt give the largest return, and with but few exceptions increased grain has resulted from applying the nitrate in small doses repeated ; the oat plots especially reveal this, and in the case of the heavily dosed barley plots the grain reaches 21s. The negative results of the three dressings in the barley series, as compared with the same quantities applied in only two dressings, may be owing to the very late period (June 28th) at which the third dose was applied. On the whole, the above trials tend to confirm an opinion I have held for some years of the advantages in favour of applying minimum doses of the nitrate from time to time as the growing crop seems to need help. I should rarely think of exceeding 1cwt. at a time, preferring even half to three-quarters if the land be in fair condition, supplementing if necessary. There is also less fear of waste, in case of immediate heavy rain washing this soluble salt away before the crop has had time to make use of most of it. Then a late spring frost will often undo much of the benefit where luxuriance is brought about too rapidly by the heavy dose 'once and for all.' A more gradual building up of the stamina of the plant is desirable, and small doses of nitrate tend this way. It often happens, too, that in the same field a portion only of the crop requires a second or third 'touching up,' and the sower is thus enabled to favour any sickening spots at discretion, so rendering the whole crop more even and level at harvest. On large holdings, especially in such a spring and summer as our last, it has been difficult enough to get through the ordinary routine of farm work without attempting *any fanciful operations* ; but I am satisfied extra care and attention in applying manures of all kinds will well repay us. There is often too much of the 'penny wise and pound foolish' policy in the slovenly way in which even ordinary farmyard manure is spread ; and one sees occasionally nitrate of soda being sown direct from the bags as imported, lumps sufficient if crushed to fertilize a rod of ground being allowed to satiate just a few plants only. I always have the nitrate passed through a fine sieve just before using it. I have tried some of the special manure distributors for sowing ; but, as the salt is so susceptible of moisture, unless the weather be very dry, it will not work freely. A double cast by hand is more to be relied upon. Equal proportions of nitrate of soda and common salt have been applied in the above series of experiments. This is a matter decidedly for local judgment.

One important fact remains to be treated, *viz.*, that the gains resulting from a top-dressing of the nitrate are almost entirely owing to the great increase of straw. This year, of course, is exceptional ; but, still, in all trials I have ever made straw has helped to swell the return materially ; in fact, at present prices for grain there would be little inducement to farm highly if our surplus straw did not command a ready sale ; but it is here that a very important question arises. At the present time of so-called 'agricultural depression,' landlords are in many cases only too willing to make any reasonable concessions to their tenants, and the granting almost universal freedom as to the growth and sale of produce is even talked about. But there is certainly no small danger of permanent mischief to the land arising from an indiscrimate use of nitrate of soda, or, in short, any of our forcing artificials, if straw is sold off the farm, and no equivalent in the shape of ordinary manure is brought on in return. Years ago, the straw grown near our largest centres mostly sufficed. Now this article is forwarded from comparatively remote parts of the country, often quite beyond the limits of a possible return of manure. Scientists have told us only recently that the direct manurial effects of straw are mostly over-rated, but apart from a chemical or simply mechanical benefit to our heavy soils, it is certainly all-important as a medium for returning the more general fertilizing constituents to the soil. In the neighbourhood of large towns straw may be sold with impunity, the same being returned in the shape of ordinary dung. We endeavour here to bring on one to two tons of dung for every load of straw sold off the farm. In the struggling endeavour to make 'both ends meet' nearly the whole of the straw has been sold off very many farms and comparatively little or no dung bought. This fact alone supplies the reason of much land getting 'below par' in condition. How far, then, a landowner is justified in granting absolute liberty to his tenant, to make free use of such forcing manures as nitrate of soda, and sell the straw, is a question of serious import. Many highly practical men are loud in their protestations against the somewhat modern practice of trusting so much to artificial manures—especially such a forcing stimulant as nitrate of soda, as peculiarly exhausting to the soil, and likely to lead to comparative

barrenness in the future. Mr. Crompton, in his valuable paper on 'Mineral Constituents,' which appeared in your last *Messenger*, also gives us a caution against indulging too freely in the use of forcing artificials, and neglecting to supply the soil with potash, &c.; and there are undoubtedly good grounds for such warnings where the old-fashioned dung-cart is in any way ignored or set aside. I have ever viewed nitrate of soda as the 'alcohol' of vegetation, and I fancy nearly every argument that can be brought forward both for and against the use of this stimulant, holds good in a sense with respect to its much-abused namesake in action. Used in extreme moderation, and from a medicinal point of view, the favourite stimulant often proves the greatest boon to ourselves, and whether animal or vegetable life be concerned, a recourse occasionally to the most severe remedial measures, stimulating or otherwise, is both necessary and beneficial. This is fully exemplified in the case of the heavily-nitrated barley plots. Certainly—believing that with a proper regard to the rotation of crops—treating my beans, pease, and root crops to a fairly liberal allowance of ordinary farmyard manure, and an occasional lime-dusting on my clover leys, I need not discard our friend 'nitrate of soda.' At any rate, it is no more my present intention to become a 'total abstainer' of the one than it is to 'sign the pledge' with regard to the other.

THE NUTRITION OF PLANTS.

IN the *Monatschrift* of the Academy of Sciences, Berlin, for July 1879, is a remarkable paper, which we have the authority of Professor Huxley for saying indicates the need of a great change in the views hitherto entertained respecting the nutrition and general physiology of plants. The subject is the action of concentrated sunlight on chlorophyll, the green colouring matter in plants, and on the plant-cell generally.

The mode of observation pursued by the writer, Herr Pringsheim, is to place the plant under examination upon the stage of an oridinary microscope, and then to concentrate the sun's rays upon it with the aid of a heliostat and 2½ inch lens. By this means an intense light can be brought to bear upon a very limited area—upon a single plant-cell or even on part of a cell, and the effects watched continuously and easily. The first effect of the intense light observed in the cell is the complete destruction of the green colouring matter. This takes place in a few minutes, and by proper arrangement can be made so local as to affect a single chlorophyll-grain or a single path in the diffused chlorophyll of an alga, all the rest of the plant remaining as green as before. This change is followed by the gradual destruction of the remaining constituents of the affected cell; cyclosis ceases; protoplasmic filaments are broken up; the arrangement of the cell contents is destroyed and their properties altered; the final result being the death and destruction of the cell, with the exception of its formed constituents—the cell-walls, the starch granules, &c.

That these results are in no way due to the *heat* of the sun's rays was shown by interposing in the path of the beam various coloured media, when it was found that a blue medium, which shut off nearly the whole of the heat rays, had no effect in stopping the destructive action, while with a red one, allowing 80 per cent. of the heat rays to pass, the cell and its chlorophyll remained quite unaltered.

Besides these experiments on the influence of coloured rays, Pringsheim tried the effect of surrounding the plants with atmospheres of various composition. The result arrived at was of great interest. *It was proved that the destructive effect of strong sunlight on the plant-cell only takes place when the plant is surrounded by an atmosphere containing oxygen; no effect is produced either in hydrogen or in a mixture of hydrogen and carbonic acid*; indeed the presence of the latter gas appears to be of no importance, as the process goes on with equal rapidity in an atmosphere from which all the carbonic acid has been removed. From these experiments the conclusion is arrived at that the destruction of chlorophyll by intense sunlight is a true process of combustion, and has no relation whatever to the decomposition of the carbonic acid in the plant. And, from the circumstance that the green colouring matter once discharged from the chlorophyll-grain, cannot be replaced, it is inferred that the process is not a normal, but a pathological one. The disintegration of the cell-contents is evidently of the same nature: that it is independent of the destruction of the chlorophyll is evident, as it takes place equally in colourless cells, such as nettle-hairs. But as long as the chlorophyll in the cell remains unaltered the protoplasm remains unaffected; so that the chlorophyll may be said to act as a protection to the protoplasm against the hurtful action of light, or in other words to diminish the intensity of the respiratory process. The absorptive power of chlorophyll, especially on *chemical rays*, confers upon it therefore the power of regulating the respiration of the plant.

In connection with the disintegration of the cell-contents, the interesting observation was made that the colourless granules which are found in the protoplasm diminished in number and disappeared during the earlier stages of the action of the light, so that probably these bodies, the exact nature of which is unknown, are the most combustible part of the cell contents, and as such are used up in ordinary respiration.

But the constituent of the cell which shows the greatest sensitiveness to light is a substance discovered by Pringsheim in the course of this inquiry, and called by him *hypochlorin* or *hypochromyl*. It is an oleaginous substance occurring in the chlorophyll-grains, and may be extracted by placing portions of plants in weak hydrochloric acid for the space of 12 to 24 hours. It is then found in the shape of semi-fluid drops, which gradually assume the form of indistinct crystaline scales, and finally of reddish-brown needles. These crystals are in all probability formed by oxidation of the hypochlorin in the chlorophyll-grains. Pringsheim considers that this remarkable substance is the "true primary assimilation-product of green plants," and that from it are formed the starch and oil in the chlorophyll-grains.—*Nineteenth Century*.

CROSS-FERTILISATION OF PLANTS.

IN Col. Wilder's presidental address to the American Pomological Society, the President, after alluding to the wonderful progress of fruit culture in the United States, proceeded as follows:—"What wonders have been achieved in the vegetable kingdom by cross-fertilisation in our own time. But still greater wonders are to be realised by this art as time advances producing new and improved varieties of still greater excellence. Instances are so numerous of wonderful improvement by the application of this art in the production of magnificent fruits, flowers, and vegetables, as to need no reference in detail. I have so often, during the forty years of my own experience, alluded to the importance of this art as a true means of rapid progress, that I refrain from extended remark and desire only to repeat my former advice—to plant the most perfect and mature seed of our very best fruits, and as the means of more rapid progress to cross-fertilise our finest fruits for still greater excellence. Thus I have discoursed to you for many years—thus I have promised to do while I live. This is our work, to direct and help Nature on in the course of improvement. Who that has witnessed the amazing improvement by the application of this art in the Rose, Camellia, Dahlia, Azalea, and other plants in our own time—who that has seen the hybrid Grapes of Rickets, Rogers, Ellwanger, and Barry, Moor, Campbell, and other practitioners, can doubt the potent influence of the cross-impregnation of plants? Who that reflects on the astonishing advance made by hybidisation of the Camellia in France and Italy, the Camellia and Azalea in Belgium, England, and France, and the improvement in the vegetable kingdom generally, can hesitate to say that this art is the great secret and source of the wonderful advance which has been achieved during the last half of the present century? Who that has seen the magnificent plants in our own conservatories, or the grand plant collections of England produced by this art, but would exclaim, 'Truly, here, at last, have we found the philosopher's stone!'"

AGRICULTURAL CHEMISTRY.

By Prof. G. C. Swallow.

IN an article in your paper of September 18th, I notice some questions propounded by Mr. W. B. Smith, which had escaped my observation. Having but little sympathy with the comments of the *Indian Agriculturist*, I think science has a satisfactory answer, which I will try to formulate.

This answer lies in the well-known properties of the soil and the atmosphere, and the habits of our corn plants and their mutual relations.

A—Chemical science teaches us that the articles of plant food exist in the soil in two states, one soluble in water and the other insoluble in water. In our white-oak soils about 90 pounds in every 100 is silica, but of these 90 pounds of silica only one-fiftieth of a pound, or about ⅓ of an ounce, is soluble in water, and available for plant food.

B—Chemistry also teaches us that the insoluble silica is rendered soluble by the chemical actions constantly going on in the soil; and that this chemical action is greatly hastened by the free access of water, heat, and air to the soil.

C—Botanical science teaches us that corn feeds largely on the silica of the soil. Every 1,000 pounds of dry corn-stalks contain 13 pounds of silica, and almost all the silica comes from the soil.

D—Botanical science teaches us that corn cannot take a particle of food from the soil until it is dissolved in water.

From these facts it is evident, 1st, that the soluble silica only is available for plant food.

2nd. That the 13 pounds of soluble silica taken from the soil for every 1,000 pounds of dry corn-stalks, would rapidly exhaust the ⅓ of an ounce of soluble silica in every 100 pounds of the soil.

3rd. That the reductions of soluble silica would gradually lessen the power of the soil to produce corn.

4th. But a year of rest, or of culture in a crop that demanded little or no silica, or a crop that is fed upon the soil or ploughed under, as Mr. Smith's clover, would increase the power of the soil to grow corn; for while the soil rested and lost no soluble silica, the constant chemical action (B) in the soil, would increase the amount of soluble silica for plant use.

The same statements would be true of other elements of plant food in the soil, as soda and potash and phosphorus; but one is sufficient to illustrate the principle.

But these principles of science "show us how it is that a crop of red clover will in three years make a soil more productive."

The exhausted soil had lost its soluble elements of plant food, and in the three years of clover, the chemical action in the soil had rendered some of the insoluble elements soluble and available for plant food. This is one reason.

Two other reasons are given by the science of botany:—

1st. Botany teaches that plants (clover among them) feed largely on the elements found in the air.

2nd. The most abundant item of plant food is carbon. Dry corn and clover contain about fifty per cent. of carbon, some of which is taken from

the air; but so much is taken from the soil that constant cropping soon exhausts what is in the soil in a soluble state.

Hence the three years of clover (ploughed in) has increased the amount of carbon in the soil by all that the clover had taken from the air, and finally deposited in the soil on decay.

And besides, clover sends its long tap roots deep into the subsoil to bring up plant food which is deposited nearer the surface when the clover decays.

Thus science gives three good reasons why the three years of red clover will increase the fertility of soils exhausted by corn:—

1st. The increase of soluble plant food by the chemical changes in the soil.

2nd. The increase of plant food by what the clover takes from the air while growing, and leaves in the soil while decaying.

3rd. The deep ploughing of the clover roots, which root up the soil to the depth of twelve or sixteen inches, bringing up the plant food, and letting in the air and heat and water, to hasten the chemical action by which the plant food is rendered soluble and available for use by the plant.

It appears to me these scientific principles answer Mr. Smith's question—"Will scientific farmers show us how it is that a crop of red clover will in three years make the land more productive?" (I leave out of the question the last four words—" than it ever was," for that so changes the question that it may or may not imply a truth, and science can never answer what is not true, or what never does occur in nature.)

There is no question that clover does improve exhausted land; and it is equally true that fallowing improves it, but not so much as clovering. —*Journal of Agriculture*, October 23.

EUPHORBIACIÆ.

THE *Times*, in a little paragraph, draws attention to a preparation which is proof against the depraved ingenuity of white-ants. Some years ago, whilst the Colonial Government of Natal was carrying on survey operations, one of the officers engaged in the work found that certain plants of the *Euphorbiaciæ* genus exuded a gum which, if smeared over knives and other steel implements, would preserve the metal from rust. Further experiments were then made. Iron plates, coated with the gum, were sunk in the notoriously foul waters of South Africa, and kept their clean surface for any length of time. Sir Andrew Clarke, then in England, had a sheet of iron coated with the gum and sunk in the waters of the Chatham Dockyard. At the end of two years the iron was taken out and found quite free from fouling or corrosion. Moreover, the gum, says the *Times*, has been tried in South Africa, and it successfully resisted the attacks of white-ants, the taste being intensely bitter and disagreeable to those insects. The Euphorbia gum is now being introduced into England. "We have examined," says the *Times*, "several applications of this composition, which gives a coating alike impervious to air or moisture; while, according to results, its own peculiar protective property remains unimpaired." Now there are over thirty kinds of *Euphorbia*,—Spurgewort, in India; surely one of these would yield the antiwhite-ant gum. The Government of India in the Agricultural Department might look up the subject.—*Pioneer*.

AGRI-HORTICULTURAL SOCIETY OF INDIA.

THE usual Monthly General Meeting was held on Thursday the 20th of November 1879.

RAJAH SUTTYANUND GHOSAL BAHADOOR,

Vice-President, in the Chair.

The proceedings of the last meeting were read and confirmed.

The following gentlemen were elected members:—

Baboo Grees Chunder Mookerjee; the Chief of Kagul, Major G. A. Way; Manager, Darjeeling Tea and Cinchona Association; Rev. H. P. Boerresen; Messrs. J. Gannon, E. P. Wood, and R. Webster.

The names of the following gentlemen were submitted for membership:—

H. F. L. Dodsworth, Esq., Oorjee Factory, Azimgurh,—proposed by the Secretary, seconded by Mr. S. H. Robinson.

Baboo Suraj Deb Narain Sing of Bulgarh, Tirhoot—proposed by Mr. T. M, Francis, seconded by the Secretary.

P. Dickens, Esq., C.S., Nuddea,—proposed by the Hon'ble L. Tottenham, seconded by Mr. Robinson.

J. M. Gordon, Esq., Hissar,—proposed by the Secretary, seconded by Mr. W. H. Cogswell.

Geo. Udney Yule, Esq., Merchant, Calcutta,—proposed by Mr. Cogswell, seconded by Mr. W. Stalkartt.

Geo. Kennett Lyon, Esq., C.S., Rungpore,—proposed by Dr. R. D. Ghose, seconded by Mr. Cogswell.

A. H. Pirie, Esq., Professor, Canning College, Lucknow,—proposed by the Secretary, seconded by Mr. Cogswell.

Koomar Maharajah of Vizianagram,—proposed by Rajah Suttyanund Ghosal, seconded by Baboo P. C. Mittra.

Rejoined,—J. C. Murray, Esq.

CONTRIBUTIONS.

1. A descriptive atlas of the eucalypti of Australia, first and second decades, by Sir Ferdinand Baron von Mueller,—from the author.

2. Report on Indian wheat, by Dr. Forbes Watson,—from the Government of India.

3. Annual Report on the Government Experimental Farms, Cawnpore and Allahabad, for 1877-78,—from the Government North-Western Provinces.

4. Report of the Commissioner of Agriculture, of the United States, for 1877,—from the Commissioner.

5. The *Indian Forester*, Vol. VI,—from the editor.

6. Proceedings of the Asiatic Society of Bengal for August 1879,—from the Society.

7. A plant of *Kigelia pinnata*,—from Mr. R. M. Daly.

8. An assortment of ferns from Ootacamund,—from Mr. F. A. Lazarus.

9. Ferns from Darjeeling,—from Mr. John Lynam.

10. Shoots of the Martaban plantain,—from Mr. C. Addy of Moulmein

11. Seed of *Panax elegans* from Queensland,—from Mr. L. A. Bernays.

12. A tree fern, Darjeeling,—from Mr. H. Kean, C.S.

13. Plants of *Bolbophyllum beccarii*, from Borneo,—from Mr. H. J. Murton, Superintendent Botanic Garden, Singapore.

14. Collections of seeds and plants from the Nicobars,—from Mr. E. H. Man.

GARDEN.

The Head Gardener's monthly report was read, of which the following are extracts:—

"The weather during the past two months has been dry, and the opportunity thus offered of cleaning up garden after the rains has been accepted as far as possible. Various rough-growing plants of little interest in any light have been cleared away with the object of supplanting them by species of greater popularity. Several common kinds of Crotons have been placed in tubs for the purpose of displaying the variegation of the leaves in the full grown plants; a few leaves of *C. Younghii* sent for inspection. [These are about two feet in length and beautifully marked.] We have a fine collection of palms and fruit trees on hand for distribution. The flower garden is being prepared, and I hope to have it ready as soon as possible. The Liberian Coffee seedlings are progressing favourably and promise to make healthy plants in a short time. A site for a new rose garden is urgently required, the most suitable place for that purpose being the central grass plot in the garden. Concerning contributions, we have received amongst others as below:—*Kigelia pinnata*—from Mr. R. M. Daly; "*Cyrtoderia fulgida*"—from Mr. J. Scott; two strong plants of 'Golden Ferns'—from Mr. W. F. Westfield.

"Of seeds, the palm seeds from Mauritius have germinated very fairly; the seeds seem to have been selected with care. The germination of vegetable and flower seeds, as far as ascertained, are herewith sent."

From the tabular statement referred to in the above report, it appears that of the English vegetable seeds five have not germinated, whilst the others (smaller seeds) have given a general average of 38 per cent. Of the American vegetable seeds, some 7 or 8 kinds have not germinated; whilst the others have given 24 per cent. Of English flower seeds, two have failed, and some of the others have yielded but a small percentage; remainder have given a fair return. The result of the acclimated (Lucknow) flower seeds has not proved satisfactory.

Letters were read from Lieut.-General Sir Arthur Phayre and Sir Ferdinand Baron von Mueller in acknowledgment of their election as Honorary Members. The Baron writes:—"I appreciate this mode of distinction all the more as I have comparatively done so little to advance the special interests of your important union; but I can assure you that I have watched with pleasure and with advantage to myself the strides made by your Society in enhancing the cultural resources of India and in diffusing a taste for refined horticultural pursuits also in the great Indian Empire."

TEA FROM YUNAN.

Mr. Locke, Secretary of the Economic Museum, forwarded for the inspection of Members a sample of "Puerh" tea, grown in the south of Yunan. The tea is stated by her Majesty's Consul at Shanghai to be "highly valued at the Court of Pekin, and by the Chinese generally, for its invigorating properties." It is also said to be "much appreciated in Thibet and to command a large market in that country." The sample in question, weighing about ten ounces, is prepared in a peculiar quoit-like form. Mr. Locke mentions that it has been submitted to a well-known Firm of Tea Brokers in Calcutta, who report on its description to the following effect—"Compressed leaf; thin, extra common, and old liquor; out of condition. This tea, in its present condition, would be unsaleable in the market. The sample must have been kept in a damp place, or come in contact with water, as it smells quite musty, like *damaged* tea."

A SUGGESTED REMEDY FOR COFFEE BLIGHTS,—PROBABLE APPLICABILITY FOR TEA BLIGHTS.

The Secretary recalled attention to the letter from Messrs. Macneill & Co., on the above subject, which was submitted at the last meeting. His application to Mr. D. Morris, the Assistant Director of the Royal Botanic Garden at Peradeniya, Ceylon, having been returned, in consequence of the departure of that gentleman for England, he had addressed Dr. Thwaytes, the Director, on the subject, who had obligingly sent him a printed copy of his remarks on the coffee leaf disease. The following extracts, which he would now read, would tend to show that the external application of sulphur is not likely to be so effective as

supposed in mitigating the ravages of coffee leaf disease. Whether it would be more efficacious in respect to tea blights remains to be seen :—

"The want of success which has attended the recent attempts to check the progress of the leaf disease by the application of sulphur and lime, seems to render it desirable that I should make some observations on the subject.

"It may be remembered that towards the end of the year 1869, the presence of some kind of disease, which proved to be the *hemileia vastarix*, was announced as present upon a few coffee plants on an estate at Madulsima. During the following year this fungus was detected at Peradeniya—a distance of about a hundred miles—and neighbouring places, still only in small quantity, but during the next year the *hemileia* occurred over considerable are as in the Central Provinces.

"The spread of the disease over such large areas in so short a time must no doubt have been due to the presence of inconceivably minute germs floating in the atmosphere and carried by the wind.

"The subsequent development of the *hemileia* filaments can have borne but a small part at first in the propagation of the pest. After a time, however, these filaments were doubtless an important element in the rapid spreading, or rather aggravation, of the disease in certain areas.

"It was to destroy these filaments with their supposed spore-producing capabilities that the treatment by sulphur and lime was adopted. This treatment though efficient in performing the work proposed, has however so far proved quite a failure in checking materially the propagation of the disease itself. Notwithstanding that the *himileia* filaments upon the plants were destroyed as expected, it soon became evident that the disease itself was not checked; for the succeeding young foliage immediately showed signs of incipient disease and this not resulting from the action of *hemileia* filaments, for those had been destroyed and none could be detected, but from some source which can only be attributed to latent infection in the coffee plants, or to the operation of the same minute germs supposed to be injuriously active during the first spread of the *hemileia* in the island.

"I am disposed to believe that *hemileia* filaments themselves do not remain in an active living state for more than one season, but that, as there is no doubt that the spores continue in a living condition for a much longer time, it is very desirable that the fallen coffee leaves, with the spores upon them, as well as the ground underneath the trees, be well treated with hot lime in order not only to benefit the trees themselves, but to kill the spores before new active development takes place to do mischief in the next season of growth.

I therefore feel it my duty to give it as my opinion that, judging from the serious effects produced, the external application of sulphur is hardly likely to be effective in curing, or in even mitigating to any very satisfactory extent the ravages of the leaf disease; and that it will have to be ascertained by very careful conscientiously conducted experiments, if any temporary benefit in the way of production of crop would be likely to result from the application of certain manures to the roots of the coffee trees."

THE ARGAN TREE OF MOROCCO.

The Secretary also recalled to the notice of members a communication on the above subject from the Director of Agriculture, N.-W. Provinces, as read at the last meeting. He had recently received a reply from the Assistant Director, Royal Gardens, Kew, to whom he had referred. Mr. Dyer writes—"The notice of the Argan tree in the *Gardener's Chronicle* is an old story taken out of the appendix to Sir Joseph Hooker's Book on Morocco. The distribution of seeds referred to took place many years ago, and we have none now to give away. If you wish to procure a supply, your best plan would be to apply to R. Drummond Hay, Esq, Vice-Consul at Mogador.

FODDER GRASSES AND OTHER ECONOMIC PLANTS.

Read a letter from J. H. Bridgman, Esq., respecting fodder grasses, of which the following are extracts. The Secretary remarked that he had already addressed Dr. Schomburgh on the subject :—

"You will remember that in April last I wrote to you quoting a passage from the *Pioneer* of the previous October, in praise of a timber tree called the *Catalpa bignonioides*. Three weeks ago the *Pioneer* had another article on the subject, from which it appears that it is extensively grown in the 'Western States' (of America)? and is 'to be' largely cultivated in Australia. Apparently Dr. Schomburgh is the authority from whom this information is derived, and for the interesting description given of the plant which represents it as one of the most valuable trees in existence. I have cut out from the paper the passage in which the information is afforded. The article refers also to other plants which I conceive will deserve your attention, particularly the fodder plants, of one of these, that which is the most praised, *viz.*, the *Panicum spectabile* you sent me some seeds some years ago, which I sowed, but the produce by no means deserved the encomiums bestowed upon it. The plant had a hard woody stalk and a harsh leaf which the cattle would hardly touch, and I gave up its cultivation in consequence. I have thought it possible that some mistake may have been made in the seed sent to me, for I think that no one could possibly describe the plant which grew in my ground as a valuable fodder plant. Dr. Schomburgh speaks so highly of it, that if there can be any doubt upon the subject, it would be quite worth trying it again."

INTRODUCTION OF INDIAN SEED POTATOS INTO GREAT BRITAIN.

Mr. Allen Stokes, a Member of the Society, submits the following extract of a gentleman of some local standing in Cork regarding seed potatos raised in India, for trial in Ireland :—

"I think we should import from some place where there is no disease, and I think you have none in India. Is this the case? and if so, will you let me know if I could manage 300 or 400 tons, the cost, the kind you would recommend, and if you can learn, would they keep for so long a voyage?"

And Mr. Stokes adds—"I shall be much obliged to you, or any of your correspondents, for any information on this point, which to the inquirer may prove of great value."

The Secretary added that he had received a communication from another member (Mr. Hindmarsh), now absent, on behalf of a friend in England, for potatos, though to a much smaller extent. Mr. Hindmarsh observes—"There has been great deficiency in all crops this year, the corn fully 30 per cent. under the average. Root crops 30 per cent., and potatos are so much diseased that in many places they are not worth lifting; in fact the absence of sunshine, a low temperature, and an excess of rain, have prevented healthy development both in farm crops and in fruit; altogether it has been a most disastrous season."

Resolved.—That these extracts be introduced in this day's proceedings with the view of eliciting information thereon.

REPORT ON JUTE RAISED IN THE VICINITY OF CALCUTTA.

Mr. Sterndale, Vice-Chairman of the Suburban Municipality, submits some fibre raised on municipal land by a native cultivator, and requests an opinion on quality and value. Mr. W. H. Cogswell, a member of the Fibre Committee, has kindly responded to this in the following words :—

"The sample of 'bun pat' jute you have sent me is well known to the natives of Bengal, being a self-sown, wild, jungly plant. It might have been much better prepared; the staple is short, irregular, very harsh, towy, but of fair strength. On such a sample it is difficult to put a correct valuation, but it is probably worth about Rs. 3 to Rs. 3-2 per bazaar maund."

Letters were read—

1. From the Director, Department of Agriculture, N.-W. Provinces, forwarding a copy of correspondence on the subject of mulberry tree cultivation, and requesting any further procurable information on the subject.

2. From the Manager, Muir Mills Company, Cawnpore, requesting information in respect to silk-worms' eggs for Australia. Mr. Smith adds—"As this is a subject that is not altogether of a personal nature, but one that may lead to beneficial results to a whole colony, I trust you will excuse my troubling you on the subject."

The Secretary intimated he had been able to meet both the above enquiries through the kind assistance of Mr. C. E. Blechynden, who had much practical knowledge on the subject.

3. From Officiating Under Secretary to the Government of India, Home and Agricultural Department, sending some further particulars regarding the cultivation of the Manilla Hemp in the Andamans.

4. From J. F. Duthie, Esq., Saharunpore, enclosing a translation from the Italian of a paper on the Carob tree (*Ceratonia siliqua*). The above two papers were transferred for the journal.

5. From the Acting Superintendent Government Farms, Madras Presidency, applying for copies of the Society's publications. To be complied with.

6. From the Director, Royal Botanic Garden, Mauritius, returning thanks for certain publications of the Society.

THE usual monthly General Meeting was held on Thursday the 18th of December 1879. The Hon'ble Louis Jackson, C.I.E., President in the Chair.

The proceedings of the last Meeting were read and confirmed. The following gentlemen were elected members :—

Messrs. H. F. L. Dodsworth; P. Dickens, C.S.; J. M. Gordon; G. U. Yule; G. K. Lyon, C. S.; A. H. Pirie; Baboo Serraj Deb Narrain Sing, and Koomar Maharajah of Vizianagram.

The names of the following gentlemen were submitted for Membership :—

James F. Smart, Esq., Manager, Balajan Factory, Noacherra Tea Co. Assam,—proposed by Dr. C. J. Simons, seconded by the Secretary.

Sheik Atta Hosen, Small Cause Court, Chowdanga,—proposed by the Secretary, seconded by Mr. W. Waterfield.

Dr. W. H. Gregg, Civil Surgeon of Hooghly,—proposed by Mr. T. E. Ravenshaw, seconded by the Secretary.

Geo. Elphinstone Keith, Esq., Merchant, Calcutta,—proposed by Mr. H. J Leitch, seconded by Mr. W. H. Cogswell.

Rejoined,—H. C. Mahony, Esq., Tea Planter, Toklai Tea Factory Jorehat, Assam.

CONTRIBUTIONS.

A further collection of seeds and plants from the Nicobars. From, E. H. Man, Esq.

A quart of the seed of *Sorghum saccharatum* From W. F. Grahame Esq, C.S.

Mr. Grahame mentions that this quantity is one-third of the product of 100 seeds sown in the beginning of the hot weather last year. One seed yielded nearly 2,400 seeds.

A case of plants from Brisbane, from L. A. Bernays, Esq., V. P., Queensland Acclimatisation Society.

Plants of Begonia *Richardia Œthiopica*, Violets and Iris. From T. M. Francis, Esq.

It was agreed, on the recommendation of the Council, that orders, similar to last season be given for vegetable and flower seeds from England and America for 1880.

Further, that an exhibition of vegetables and fruits and flowers be held early part of next year, the former in January and the latter in February.

GARDEN.

The Head Gardener's monthly report was submitted as follows :—

"The weather in regard to temperature has been seasonable, but the rainfall has been insufficient for successful garden operations. The principal labour in the garden has been taking off Rose layers, and

layers of various other ornamental plants and potting off young plants which have been propagated. We commenced repairing the principal paths throughout the garden sometime ago, the huge brickbats, which prevented the paths being travelled over with any comfort have been removed from the centre of the path, and are being utilized for a new road in course of construction in the south-east corner of the garden, to an old gateway there ; this road will be very useful as manure and house rubbish, on arrival will be deposited in the rubbish yard adjacent to this road, and thus save the cutting up by the carts of the garden paths after repair. We have also been engaged cutting and clearing away various shrubs of jungle origin which, though they might have been found useful at first for the purpose of filling up bare spaces, can be spared now with advantage. Seeds have been sown in south flower garden and are germinating well. Various kinds of annuals, sown sometime ago, have been planted out in suitable places around the grounds. Many of the large beds around the lawn which, up to the present, have been occupied with inconspicuous plants in regard to beauty, have been planted out with large sized Crotons, which, when well into growth, will prove very effective. Sowings of various contributed seeds have been carried out as usual and also the potting of those which have germinated. We have reported the young plants of the forbidden fruit which were raised from seed supplied by Col. W. M. Lees in 1878-79. At first, on germination, many of the seedlings were entirely denuded of leaves by the larvæ of *Papilio Pammon*, and in consequence many died ; still we have been able to save about 113 plants, which are ready for distribution. We have also a nice lot of *Pithecolbium Saman* plants, just suitable for planting out. I omitted to men ion that the road leading from the Belvedere grounds on the north-east has also been newly laid. Concerning the ferns presented by Mr. F. Lazarus, a few are doing fairly, but somehow the ferns sent us from Darjeeling by Mr. J. Lynam, have unfortunately not succeeded. This, I am surprised at, as they seemed so fresh on arrival and have moreover had the same treatment and position as the others. Contributions during the month were as follows :—The tenth consignment of Andaman seeds, of which the *Palmaceæ* and *Pandanaceæ* germinate fairly ; other miscellaneous seeds have not succeeded so well. A small collection of bulbs from Mr. Bull which have been duly potted off. A collection of choice flower seeds from Messrs. Sutton and Sons of Reading, sown in south flower garden. Palm seeds from Mauritius Botanic Garden also sown. A climbing fern (Lygodium?) sent by Mr. O. H. Brookes, Andaman. A case of Cotton cuttings from the Queensland Acclimatisation Society ; many of these are rooted slightly, but have lost all their foliage. If slight ventilation had been provided for, I think they would have arrived in better condition. Also received 6 plants of *Poivrea coccinea* presented by Mr. G. D. Vere, Bhowanipore."

Tea from the Andamans.

A report from Messrs. Moran & Co., altogether favorable, on a sample of tea from the Andamans, forwarded by Mr. O. H. Brookes, Settlement Officer, was submitted. It was agreed that this sample, the first received of the growth of the Andamans, be transferred for deposit in the Economic Museum.

Fibre from Kumaon.

Mr. J. G. Bellairs, of Chowkooree Tea Factory, Almora, Kumaon, submitted certain samples of fibre and a small specimen of cloth made therefrom, with the following remarks thereon :—

"I am sending you down by post to-day samples of a fibre procured from a plant grown on this estate, and shall be glad to know what you think of the fibre, and whether in your opinion it would sell in Calcutta or London and at what price.

"Sample C. is the fibre ready for market unhackelled.

"Sample A. is the fibre after hackelling.

"Sample B. is Tow taken out of A. in hackelling, it has not been whipped.

"I have tested the fibre against that of rhea, and find what I send you far the strongest and for work under water. I question if anything will impair it ; *carefully* twist up a thread to say No. 50 cotton size ; and you will have some idea of the strength of the fibre. Fishing twine made of it. I find stronger and more lasting than any English made line I have ever seen weight for weight and length for length. For working up into dress stuff alone or with other material, I think the fibre will prove of value. I am now making in a rough loom coarse cloth, and a sample I will later on send you.

"I am prepared to place a few tons of the fibre on the London market, if the reports I receive on the fibre lead me to think the venture likely to succeed, and if the trial shipment paid, I could send any quantity yearly, as the plant from which the fibre is taken grows most kindly in this soil, in fact the quantity will be merely a question of capital."

Read the following minutes of the Fibre Committee on the above samples :—

Mr. John Stalkartt.—I believe this fibre is obtained from a species of nettle and have seen something like it in the Darjeeling Hills, but there it was very difficult to clean.

I think it very valuable, and that it ought to be sent to England for valuation to some silk factory, or to some of the makers of the higher description of linen or fancy goods, articles that ladies wear.

Mr. S. H. Robinson.—This is no doubt from one of the nettle tribe, very like rhea, but the crushed fibre is coarser, about double the size of the rhea under the microscope. The question as to its economical value depends entirely on the cost of its production, and Mr. Bellairs should let us know at what price per maund it could be laid down in Calcutta ; it is much too coarse for use as cotton, but could probably be put to the same uses as rhea.

Mr. W. H. Cogswell.—I think the fibre is produced from the nettle, which in some of the Hill districts, grows to a great extent and is very luxuriant in the rainy season. It has been well prepared, but I think the colour might have been improved on. It is of good length, very soft, almost silky, and of great strength. I have not a sample of rhea fibre by me for comparison, but I am of opinion that this is not so valuable as the rhea.

It would be unsaleable in this market, but I recommend a very large sample shipment of it to be made to London to some flax-spinner, whose opinion would be valuable in all respects and its correct value readily ascertained. It ought to pay as a cultivation, but Mr. Bellairs will doubtless furnish the Society with some details and also a specimen of the plant, with its flower also, if possible.

Resolved.—That copies of the above be sent to Mr. Bellairs, and his attention requested to the recommendations contained therein.

Tea Blights.

Read the following extract of a letter from Mr. A Grote, in reference to the specimens of blights and insects referred to in the Proceedings of June and July last:—

"I saw Mr. Moore to-day and shewed him the specimens of blights and insects enclosed in your tin box. The so-called blight sent to you by Mr. Pinney is the larva of a Flata which covers itself with those long white plumes. It is an Homopterous insect allied to the wax insect of China, and the plumed larva is always to be found in the insect collections sent down in boxes from Eastern Bengal. Feeding as it does, on jungle plants, it will prove probably to have been only an accidental visitor to Mr. Pinney's tea garden.

"The green beetle sent to you by the Munguldye Company is a Curculio allied as Moore thinks to C. tanymecus, but these beetles ordinarily bore into the stems and branches of plants and do not meddle with their leaves. Of these last you sent me some specimens, which undoubtedly had been pierced by insects ; but is it certain that this particular beetle did the mischief ? Our scientific Committee has not yet commenced its sittings, and I have therefore been unable to consult them. Still the whole family of weevils should, if possible be kept out of Tea Gardens. I hope Mr. Pinney and the Munguldye Manager will keep you informed if these pests show themselves a second year."

In connection with the above, the Secretary submitted the following extract of a letter from the Manager of the Kunchunpore Tea Company, (Cachar) regarding the Mosquito blight :—

"With reference to your letter of the 14th instant, regarding the cure of blight on the Lydicherra Tea Estate, by cutting the jungle round the tea, I beg to inform you it has been tried on various gardens without the least effect every year since 1867, and the Estate mentioned not having suffered severely this year, is one of the peculiarities of blight which baffles all attempts at understanding it. I know gardens that have no jungle whatever round the tea, it having been all cleared out, yet the blight is as bad, as when the jungle was there. With reference to next year, I have not experienced two successive years of severe blight, and there is no doubt the drought, &c., had a great deal to do with its being so severe, and we are not likely to have two successive bad seasons either : a good one has hitherto followed a bad, as witness 1867, 1868, 1870, 1871, 1875, and 1876. With reference to the cure of blight all we have found out is, that it is an insect resembling the mosquito, and as numerous ; any number can be seen any day sucking the juice of the young leaves, but where it lives, lays its eggs, &c., and at what season, is only a conjecture. The loss by this pest is so enormous, that those interested in tea should combine and get a first class Entomologist to reside for a season in the tea districts and study and find out the habits, &c., of the insect ; that known I think, the cure would easily be found, and I think it is the first thing to be done. I know Managers who would forfeit six months' pay if they did not make over a third more tea if blight was cured, and I know Companies who lose from 40,000 to 50,000 annually by blight alone."

Value of the Juice of Euphorbia as a Protection for Iron-Work.

Read a letter from Col. W. M. Lees, dated Torquay, 6th November, of which the following is an extract:—

"I send you a cutting from the *Times*, as I am under the impression that some of the *Euphorbiaceæ*, grow as a weed in India, and as I remember some rather costly experiments being made at Calcutta to protect iron against corrosion and marine growth, the subject might be worth considering."

"The Euphorbia.—Some few years since a survey was being carried out in Natal for the Colonial Government, during which it was discovered by one of the officers engaged on the work, that when certain plants belonging to the natural order *Euphorbiaceæ* were cut with the clearing knives, the gum which exuded from the plants adhered firmly to the blades, and was very difficult to remove. It was moreover found that the knives so coated, did not rust, and this led to further experiments being made with the view of utilizing the gum as a preservative material. Iron plates were coated with the gum and subjected to immersion in the waters of South Africa, which are stated to be proverbial for their foulness, and for the rapidity of the growth of vegetation. The Euphorbia in Natal grows in close contiguity to the seashore, so that there was ample opportunity for securely testing its value as a protective covering for iron against corrosion and main growth. The experiments proving perfectly successful, it was then sought to put the discovery into a practical form. To this end the gum was dissolved in a preparation of sprits, and this was found to be a ready means of applying it as a coating for ships bottoms and for ironwork generally requiring such protection, the spirits evaporating and the gum being left on the surface of the metal. With this preparation, experiments were made a few years since by Sir. Andrew Clark, C.B., who had a sheet of iron coated with it and placed in the waters in her Majesty's dockyard at Chatham, where anything immersed becomes rapidly fouled. At the end of two years the sheet of iron was taken out and was found to be quite clean, and free from fouling and corrosion. The composition has also been successfully tested in Africa against the ravages of the white-ants. This success is attributed to the circumstance that the gum of the Euphorbia, which from the base of the fluid, is of such an intensely bitter nature, that it paralyzes the efforts of all insects to attach themselves to it, or to bore into any substance coated with it. These successes have led to its adoption in practice for the purposes above indicated, and it is now being introduced in England. We have examined several applications of this composition, which gives a glossy coating alike impervious to air or moisture, while,

according to results, its own peculiar protective property remains unimpaired."

Letters were read—

From Under-Secretary Government of India, Home, Revenue, and Agricultural Department, forwarding copy of a communication from H. B. Majesty's Consul at Manilla, regarding the cultivation of the *Musa textilis*.

From the same, a report from the Director, Department of Agriculture, N.-W. P., on the experimental cultivation of *Euchlæna luxurians* during the year 1878-79.

From the Director, Department of Agriculture, N.-W. P., respecting a process of grafting as communicated by the Superintendent of the Government Farm at Allahabad.

The above were transferred for publication in the journal.

Mr. W. Chick forwarded for the inspection of the Meeting one of his "patent economic ploughs," cost Rs. 11-8. Mr. Chick states that this plough weighs only 85lb, as against a hundredweight, the average minimum weight of an English plough. Though more expensive than the primitive plough of the country, he remarks that it will last four times longer, and can be easily drawn by native cattle.

MINERALOGY.

IN August last considerable interest was excited at home by the Indian Gold Mines Company which is probably the Company that Reuter told us lately had been formed in London, with a capital of £100,000 for the purpose of working the gold mines in the Wynaad. The Company hold the lease of the Seeputtee estates and other mining rights assigned by the trustees of the late firm of Messrs. Nicol & Co. and Messrs. Smith, Fleming & Co. For the rights they leased, the trustees were to receive £10,000 on completion of the assignment, and after the preliminary expenses had been repaid, the profits "up to £4,000,000 sterling" were to be applied as follows :—"50 per cent. to the trustees of Nicol & Co., and Smith, Fleming & Co., and 50 per cent. to the Company; and after the £4,000,000 of profit had been divided, 50 per cent. was to belong to the Company, 20 per cent. should be paid to the trustees, and 30 per cent. to the liquidators to the City of Glasgow Bank; but when the liquidators had received £5,000,000, the profits were to be divided equally between the trustees and the Company." These details of the agreement appeared incidentally in the course of a law suit, and may perhaps now be modified, but the formation of the Company seems to be an actual fact. If the capital has all been subscribed, as we are led to suppose by the telegram, the Wynaad gold field will be tested at last in a business-like manner, by the most capable experts, provided with the best appliances, and a problem that has dazzled one or two generations of speculators will be solved one way or the other.

FORESTRY.

THE French Forestry Department, according to the *Polybiblion*, are satisfying themselves that forests directly increase the supply of water in their neighbourhood. From observations at Senlis and Nancy, they have decided that it rains more abundantly in wooded tracts, and that, while the leaves and branches give back the water quickly to the air, they prevent rapid evaporation from the ground, and are thus favourable to the formation of springs.

IN 1878 there were imported into Great Britain 60,254 loads of oak, of the estimated value of £354,916, against 120,118 loads in the previous year, being a decrease of 59,864 loads. The various oak producing countries contributed as follows :—Russia, 3,151 loads; Germany, 25,048 loads; Austria, 3,014 loads; United States, 2,641 loads; British America, 25,402 loads; other countries, 998 loads. Last year, 37,990 loads of teak were imported to Great Britain, against 28,072 loads in 1877, showing an increase of 9,918 loads.—*Timber Trades Journal.*

NATIVE FORESTERS.

THE following extracts are from a resolution of the Government of India in the Home, Revenue, and Agricultural Department, dated the 23rd October :—

For the sons of native gentlemen and for other well-educated natives of India, there are two modes of obtaining access to the controlling branch of the forest service; either by passing the entrance examination at the India Office, and going through the prescribed course of professional education in Europe, or by obtaining admission to the executive staff, and afterwards earning their promotion to the controlling staff by distinguished service as executive officers.

A Central Forest School has been established chiefly to make it easier for the sons of native gentlemen, and of youths of other classes who have received a good school education, to acquire within a comparatively short time that amount of practical skill and theoretical knowledge which constitutes the professional training necessary for the executive staff. At the outset a minimum of educational acquirements is demanded from candidates, comprising only the ability to read and write, the elements of arithmetic, and a good knowledge of accounts. But this is only the minimum of requirements laid down, and it is left to local Governments to raise these gradually with the view of demanding eventually a good school education as an indispensable condition for the admission of apprentices to the Forest School.

It is hoped that young men of good education will be encouraged to seek the post of forest ranger. It has been thought that among the existing forest rangers some men may be found of superior qualifications and acquirements which may fit them to rise to the superior staff. It is also probable that there may be cases of young men of good social standing, sons of native gentlemen with a superior education, and possessing special qualifications for the forest service. The orders contained in the Circular Resolution No. 29 F, dated the 5th August last, were intended to meet such cases. In order, however, to provide more fully for the case of forest rangers possessing qualifications for promotion, as well as for that of native gentlemen not in the forest service, a revised memorandum of conditions has been framed which will regulate their admission and subsequent employment. This memorandum lays down that :—

The following classes of persons may be admitted as probationers :—

(a) Forest rangers and other forest officers in positions corresponding to that of Forest Ranger.

(b) Native gentlemen of good position and education who are not in the forest service.

Candidates should personally submit their applications to the Conservator under whom they are serving, or of the province to which they belong, as the case may be. Candidates residing in Native States may submit their application to the Conservator of the nearest British province.

In the case of candidates already employed in the forest service, the maximum limit of age will be 30 years, but in special cases of unusual merit exceptions may be made. Other candidates will only be accepted if above 18 and below 25 years of age.

Candidates must submit the following papers :—

1st.—A statement of their names and parentage, and a birth certificate or other satisfactory evidence of their age.

2nd.—A medical certificate of good health and constitution including good eye-sight and hearing, signed by a Presidency Surgeon or the Civil Surgeon of the station nearest to his place of residence.

3rd.—A statement of the schools and colleges at which they were educated since they were twelve years of age, together with a certificate of having passed the entrance examination at one of the Indian Universities, or such other examination as the Conservator may consider sufficient.

In case the Conservator is not satisfied with the certificate offered, he may require the candidate to pass an examination in the following subjects :—

I.—Orthography, to be tested by dictation of not less than one octavo page from a standard English author.

II.—English composition, to be tested by writing a letter or report on some general subject.

III.—Arithmetic in all its branches.

In such cases the examination will be conducted either by the Conservator of Forests to whom the application was made, or by the Principal of a College, or such other educational officer as the local Government may direct.

It will rest with the Conservator forwarding the application to decide whether the result of the examination is satisfactory, or, if he prefers it, he may consult the Director of the Forest School.

4th.—A certificate of qualification in surveying by the lower standard as laid down in paragraph 14 of the Forest Department Code.

The Conservator must satisfy himself that the candidate is proficient in the languages of the province in which he submits his application.

The names of candidates whose applications are accepted by the local Government will be registered, but registration does not imply any promise of appointment. Candidates will be eligible for appointments in the event of vacancies occurring.

They will be appointed as probationers, and will generally be sent to the Central Forest School at Dehra Dun for training in the School Forests during a period of two years. Should in any special case the local Government desire to employ any probationer at once instead of sending him to the Forest School, this may be done with the sanction in each case of the Governor-General in Council. In such cases the period of probation will be two years, and the conditions for admission to the superior staff will be similar to those fixed for probationers who are sent to the Forest School.

Probationers already holding appointments in the forest service will draw the pay of their grade, provided that the amount does not exceed Rs. 150 a month. Probationers not being in the forest service will draw such pay, not exceeding Rs. 100 a month, as may be fixed by the Conservator of forests by whom they were selected, in communication with the Director of the Forest School.

Half-yearly reports regarding the progress and qualifications of all probationers at the Forest School will be submitted on the 1st April and 1st October in each year to the Conservator by whom they were selected. The Conservator will forward these reports to the local Government.—*Pioneer*, 27th November.

THE GARDEN.

PÆONIES.

NO flowering plants capable of enduring our northern winters are more satisfactory than the Pæonies. Massive without being coarse, fragrant without being pungent, grand without being gaudy, various in form and colour beyond the possibility of being successfully superseded, they stand in the first rank of hardy flowers. They are derived principally from four species, each of which is beautiful—P. moutan, P. Sinensis, P. officinalis, P. paradoxa. A few varieties are from species of less importance. The Pæony belongs to the natural order Ranunculaceæ, which fact alone is a warrant of its worth.

I have had much experience in ordering Pæonies from catalogue description, and it has been so expensive, and the result so vexatious that I have about reached the conclusion that colour-blindness, carelessness, or worse, are all that is needed to write a descriptive catalogue of them. I have rejected a good load of roots, after giving them a trial; not that they were inferior in any way, but because I had others so near like them, that I could not readily tell one from the other. The object of this article is to call the attention of amateurs to some varieties which are particularly fine, and which differ enough from each other to give satisfaction. The old Pæony, officinalis, is the parent of several varieties. Of these rubra is a bright crimson and grandiflora rosea is of bright rose colour. These sorts are old and grand; but whoever discards them on account of their being old will make a sad mistake. P. officinalis tenuifolia fl. pl. is a floral treasure, though I do not believe that it is a variety of officinalis, as it has all the traits of a distinct species. It blooms early; its flowers are double and of a bright scarlet-crimson colour. Even without flowers it is a beauty, on account of its delicate fern-like foliage. Though this variety is perfectly hardy and easily grown, it does not seem to be very plentiful.

P. paradoxa.—The varieties in this division originated in Europe. The best is Nemesis. The flowers are very numerous and full, but quite small and of a rich crimson colour. All the varieties of P. paradoxa are crimson, of greater or less intensity.

P. moutan differs from all the others in having a shrubby top. There are no decided colours in this division; but a simple range of shades, from a dim white to a dim rose. Some of the flowers are very good; and, as they are borne on bushes or trees from 3 to 8 feet in height, they are quite conspicuous. The best white is Bijou de Chusa, and the best coloured is Cumpperii, a bright rosy-pink. I say to the amateur: Don't be in haste about getting Tree Pæonies, for the best are not yet in market.

For brilliancy, grace, and fragrance, the varieties from P. Sinensis must have the first place, as they may be had in a greater variety of shades and colours than those of any other class.

Bicolor is a handsome variety; outside rose-colour and the centre of a very good yellow. Festiva is pure white and very full.

P. fragrans, sometimes called the Rose Pæony, is one of the best. It is of a rose colour and very sweet. P. Humei resembles it in colour, but blooms much later and is the latest of all I have tried. Jules le Bon is a bright red. Mrs. Dagg is a very early variety, dwarf habit; flowers pure white, dotted with red. Perfecta, outside petals a peculiar shade of pink, inside petals lively salmon—a beauty.

P. purpurea superba is of a deep brilliant crimson. The plant a tall grower and very showy.

After getting more kinds than I have mentioned, the distinctions will begin to disappear between those you have and those you get. In making a selection, I would especially caution the amateur, when he takes up a descriptive catalogue of Pæonies, against making any great distinction between the colours which he finds mentioned as pink, rose, and lilac. Whoever considers these colours as differing much from each other will discover the true distinction when he sees the plant in bloom. A very good way is to let some reliable grower make a selection for you, as such a person takes pains to propagate the best varieties largely, and it often happens that he has a surplus of the best.

In raising Pæonies from seed, the seed should be soaked in water for a day or two, as it is very hard. About March 1, it should be sown in a brisk heat, and when the weather becomes warm the seedlings may be planted out, and will show their colour, the third year. They are usually increased by dividing the root; and, though this is commonly done in the autumn, there is nothing gained by it. March or April is a better time, as the new root will have a chance to get hold of the soil before it is called upon to endure our northern winter. The soil in which they are planted should be dry, rich, and deeply dug. The tubers should be planted 6 inches deep.

P. moutan is propagated by grafting on the root of P. Sinensis, and by an amateur may be performed as follows:—In the spring take some good strong single roots from the clumps of some Chinese variety, and plant them by themselves in a nice place, and grow them until September. Then cut a scion from P. moutan. It should be about 3 inches in length, and contain a bud. Sharpen it, and insert it firmly in the root which is used for the stock, and cover it with the earth that has been thrown out to make the experiment; and if the work has been carefully done, the graft will take care of itself.—*T. Independent.*

TEA.

IT is much to be regretted that the sudden rise in tea prices, which took place a couple of months ago, has not been maintained at later sales, and this decline has naturally re-acted on the Calcutta market, where prices have fallen to their old level, a level which leaves a very small margin for profit to the planters.

WE would direct attention to an interesting letter from NONDESCRIPT on the subject of *rasping* tea. Our contention is, not that this class of teas *per se* realises smaller prices than teas more perfectly manufactured would, as most likely, in the present state of the market they are fetching as high rates as any other quality would. Our argument is that the system is "ruinous," because it prevents Indian tea being properly known by the people at home, and in this way hinders its introduction as an article of commerce. It is beyond all cavil true, that Indian tea is liked wherever it is introduced in a pure state to the consumer, who is prepared to pay more for it than for China. Regarding our correspondent's reference to wine mixing, he is clearly looking at it from a wine merchant's point of view. We look at these subjects from a manufacturer and grower's standpoint, and to carry out his illustration, what would be thought of the wine grower who, with a view to secure the market hinted at by our correspondent, should devote his attention to making a crude wine for the purpose of enabling merchants to improve their "inferior liquors," and who by so doing would infallibly ruin his own name and mark. We do not think that there is any ground for anticipating ruin to the planting interest, from a universal and permanent reduction in prices, as we affirm that tea ought not to cost more than eight annas per pound, and should as a rule be made at a cost of from 4 to 6 annas, and that the day is not far distant when these will be the manufacturing charges. This economy will be effected by a severe wrench being given to those vested interests, which are at the present day helping to crush this rising industry, but which will be swept away as encumbrancies, under that pressure which permanently low prices will exert.

IN a recent tea circular, Messrs. Balmer Lawrie & Co. review the past season as follows:—"The year 1879 will long be marked and remembered as one of the most extraordinary experienced by tea planters: all districts had somewhat similar weather; a hot dry spring, and late commencement of the season; excessively wet June, July, and August; fairly favourable weather in September, a good October, a dry November, and an early close; the tea suffered seriously during the hot weather in the early part of the season, while the incessant rain that followed, being unaccompanied by a sufficiency of sunshine, produced leaf surcharged with water, and wanting the essential constituents for making good *strong* tea; all the early shipments were classed as weak, and there was little change until September; a difficulty in withering during the dull cloudy days and cold nights may have increased the evil; but the main cause of the bad weak teas seems to have been the want of strong sap in the leaf. As regards quantity, the outturn for the season will not nearly come up to estimates; looking at shipments to end of November, and taking into consideration that nearly all Darjeeling tea is down, while Assam and Cachar have probably less tea to send than they had last year, we the quantity avaliable for export will probably be well within think 37,000,000lb.; possibly not more than 36,000,000lb. Notable features resulting from the unfavourable weather are the check given to transplants and young bushes, the bad crop of seed, and the prevalence of blight."

IN reviewing the state of the tea market last month, Messrs. J. C. Sillar & Co. remark that the rise in prices within a very short period is about £2,000,000, and oddly observe (evidently at the dictation of the senior partner, whose peculiar views on Indian and Eastern matters are notorious):—"When we reflect that this sum of money has to be paid by the public, and the greater portion of it has gone into the hands of the usurers, who have been primarily instrumental in destroying the importing trade, we will see the wisdom of the laws of the Christian Church, which condemn the sin and the responsibility which rests with the bishops and clergy for allowing these laws to become a dead-letter." Returning to business, the firm explain that the oldest and most experienced authorities in the China trade adhere to the opinion

that the total shipments for the season will fall short of those of last year by 12,000,000lb., which will make the total export not more than 153,000,000lb., or 2,000,000 less than previous estimates. Nineteen and-a-quarter million pounds of tea were sent this year from Foochow and Hankow to the northern ports for transmission to Siberia, Russia, &c., against about eight millions last year. This will partly account for the falling off in the exports to England ; and, should speculation be renewed, we may see Mincing-lane in the state the Liverpool Exchange was a few weeks ago—"more like a race course than a mercantile exchange." Messrs. Sillar say that teas are still sold on the time-bargain system ; that is to say, purchases made to-day need not be concluded until the 15th of February next year, usury and other deductions being allowed to the buyer as before. The gambling has extended to the cargoes of vessels now on their way from China, and we hear of sales to arrive which show a profit of fifty per cent. upon the invoice cost.

A VISIT TO THE TEA DISTRICTS BY F. E. D.

IN a former paper I stated what appears to me the principal reasons why tea does not pay in the present depressed state of the market. As some readers may not have seen that paper, I may briefly repeat that these reasons are—the little work coolies do for their wages, and the want of unity amongst planters in matters relating to the labour.

My description of the works I saw progressing, showed that the tasks are usually such as a cooly can complete in five hours, and it is to this matter I should like those interested in tea to give attention. On some gardens these light tasks had so long been customary that nothing was thought of the matter by the manager ; on others, the lightness of the tasks was a ground of complaint, but in these cases there seemed no remedy, except with the risk of losing the cooly as soon as his agreement expired ; but what was done in some cases was to compel the men to go out in the afternoon and hoe *ticca*, for which they were paid extra sums from 2 annas to 4 annas per diem. This, while keeping the garden clean, allows the cooly to save a considerably larger amount than would otherwise be the case ; and after three or four years he is able to take up a piece of rice land and settle down as an independent man ; so while combating one evil another is created, and it appears to me that until there is more unity amongst the planters, there is little hope of radical improvement. Improvement, however, is possible, and I would recommend those planters who find their coolies with so much time on their hands, to see that there is no room left for improvement in the style in which the present task is performed, in preference to increasing the task by measurement. For in the work of cultivation in too many cases I noticed that the area got over was primary to any other consideration, and while the task (one cottah) is a fair day's work, if done well, it is equally a very poor one when coolies are allowed to get through it according to their own ideas. Complaints of the labour-task being too small were pretty general, but I noticed that some gardens were kept in better order with a proportionately smaller number of coolies than others under different management. This may be the result of one or many causes—smaller yield per acre, &c.,—but I satisfied myself as to the principal cause, and found it was superior cultivation. Whereas it is the rule to give the ground a light chop 2 or 3 inches deep, leaving all the weeds on the surface. I found the exception a good deep cut and turn over, which *buried* the majority of the weeds, and consequently the land remained much longer clean. That the latter style is not general, is somewhat surprising ; for while we are trying to impress on the native cultivator the advantages of deep cultivation, on gardens under European supervision, our own maxims are lost sight of. I believe the gardens do receive a deep hoeing in the cold season, but it seems clear in theory—and I believe it would also be found in practice—that deep cultivation during the rains would be much more profitable. We have from the best authorities the opinion that tea requires a light, well-drained soil. It is certain Nature, when forming some of the sites, forgot the drainage, and it is for the planter to supply the want. Already some of the gardens are a net-work of drains ; but with no intention of under-rating the value of these, I would recommend *deep cultivation* ; water will find its own level, and when assisted through the surface soil, for which nothing is more effective than keeping this soft and light by deep hoeing, it will flow on in its natural channels. That the gardens are now supplied with labour sufficient for deeper cultivation during the rains is without doubt, with the exception of some gardens, where the coolies light hoe 1½ cottah per task. The difference in a 7-hours' task and a 5-hours', one is just 40 per cent., and I am sure this would be about the saving on the cultivation charges, for the garden will keep clean longer and the leaf yield more abundantly. The earnings for plucking extra leaf, I consider out of all proportion to the work done. Allowing the months—May to October—to be the harvest, rates that allow a woman to double her wages for six months of the year call for reform. If these people were out from sunrise to sunset plucking quickly, they would be entitled to extra remuneration ; but as a rule, I found it was half-past 6 A.M., before they commenced plucking ; about 5 P.M. they were called in, having had two hours' leave at mid-day, so that they performed a day's work of only 8½ hours,—half an hour *less* than the working day laid down by Government in Act VII. of 1873.

But as I before stated, radical reform without risk of losing the coolies, is impracticable, until there is unity amongst the planters. The whole of the mischief appears to hinge on the competition for labour, especially the practice of taking it from neighbouring gardens, and I believe this is to be the principal reason why so many estates cannot pay their expenses, as well as of the present low prices which tea realizes. The practice unsettles the cooly, and the planter, for fear of losing him, is less particular in looking to the style of work performed. Take, again, the system of giving a present and extra pay, equivalent to Rs. 2 or Rs. 2-8 to coolies who renew their agreements. Could the planter be sure of getting good "Junglies," it would be cheaper to import direct from Bengal. If there is one set of men more to blame than the other for the above state of things, it is small capitalists, or, more correctly speaking, men who open out a garden *without* capital ; men who start with a few hundred acres of land, which the present rules enable them to take up at a small cost, with some seed, and as many time-expired coolies and village labourers as they can get from gardens in the vicinity, trusting to their appointment as Manager of some company not far off to pay the monthly expenses. This charge may be thought malicious, but I can assure the reader there is nothing further from my mind than malice ; I frame it solely on information gathered, to the effect that not 5 per cent. of these small gardens import a cooly until their third or fourth year. In some cases the sanction of the proprietors or directors, as the case may be, is obtained before these gardens are commenced ; others are carried on for years without any information being given ; but the evil in both cases is equal. When sanction has been given it cannot be rescinded; but in the other case proprietors have the matter in their own hands, and precedents are not wanting where managers have been given a specified time in which to decide on the alternative either of retaining their appointment and giving up their private interests, or preparing to give the latter their undivided attention. Supposing tea capitalists could get these small gardens amalgamated with larger ones, or import their own Bengallee coolies, there would still be much room for improvement ; but an influential association of those interested is required to bring even this about. This should be formed in Calcutta, where tea is represented by comparatively few individuals ; branches should also be formed in the several districts. Independent local associations will never be formed judging from the accounts I have heard of some of the attempts in that direction. The crying want is a leading man, but when you find him he has already too much on his hands. The subject for first discussion should be the best means to stop the systematic practice, as it is in some cases, of inducing coolies to leave the garden for which they are imported. An order from the agents or secretary would in all cases stop direct enticement ; but this alone will not meet the case. Many planters who would not stoop to send out men with sums of money, and instructions to get as many of their neighbour's coolies as possible, promising a reward for each one brought, study the best means to attract coolies to their gardens of their own accord. For instance, one planter will supply his time-expired coolies with rice at Rs. 3 per maund, another will give a higher bonus or present to coolies when renewing their agreements, while others look to the lightness of their tasks as an inducement for coolies to go to them. These are the matters for first settlement, and when settled effectually, great good will be the result. The large percentage of coolies who abscond should also be a subject for discussion. To every inquiry,—"What becomes of these people?" the answer was "Goodness knows," or something equally vague. Possibly many find their way to small gardens in out-of-the-way places, but the hundreds who abscond during the year, as shown by the Government statistics, cannot be accounted for in this way. A cooly came under my notice who had absconded and been apprehended *three times*. I inquired "Why do you not have the man sent to jail?" The answer was :—"I have sent coolies there who have returned and absconded again almost immediately after : the jail is no deterrent to this class of men." From further information I believe this to be the general opinion. Now, instead of Government filling the jails with such people, would it not be better if the first time a cooly absconded, as soon as he is apprehended, he were taken before a Magistrate, the number of days he has absented himself endorsed on his agreement, and warned that in case of another conviction he will get a number of stripes.

This subject might be much enlarged upon, but I leave it to abler pens to do so, feeling sure all will agree that the matters I have referred to call for urgent reform. It is doubtless a matter of opinion, but to me it seems preposterous that labourers imported into the tea districts, at a cost of Rs. 90 to Rs. 100 per head, who often enough present themselves at the depôts hungry and almost nude, should after three or four years on a garden be semi or wholly independent, having in this time saved enough money to purchase cattle and settle down on Government land to cultivate on their own account. At the same time we find gardens just paying their working expenses, or in many cases working at a loss. Why should time-expired coolies, who receive a present and extra pay of Rs. 2 per month, receive rice from the factory godown at Rs. 3 per maund, when it often costs Rs. 5 to place it there? Simply because any Manager who takes the laid down cost, risks the loss of his cooly, who is almost sure to go to a neighbour

who supplies rice at Rs. 3. Matters of this kind require united action, and a great saving might be effected without being unjust or hard on the cooly.

I have only one little matter left to notice; this relates to the manufacture of the tea. There appears to be a great difference of opinion on some of the details. One planter will insist on the necessity of rolling his leaf twice; another will half roll, sift out the finer leaves, then finish the rolling; another requires his leaf to be fermented in balls, and so on. The most casual observer could not help observing that these manipulations require extra labour, and the first question is, are they necessary for the better manufacture of the tea? If so, by all means carry them on. If not, the labour should be otherwise utilised. The question must be answered by some one able to decide. Unless the Manager is prepared to remain in his tea-house whilst the tea is being manufactured, I would recommend him to simplify the process by every possible means.—*Statesman and Friend of India.*

CALCUTTA, 10*th December* 1879.

TEA CULTIVATION IN CEYLON.

WE attract attention to this interesting and practical paper.—ED., *Ceylon Observer.*

(Communicated.)

Inquiries are on people's lips (as these columns recently testify) as to what is the position and what are the prospects of this enterprise.

The following remarks are offered by one who has had an interest in tea for nearly three years, and who has had opportunities of observing tea cultivation in India.

There can be no question that in the normal state of the tea market, tea cultivation pays most handsomely where the conditions are favourable for obtaining a good yield and for working economically. That these statements may not be considered too broad let it be understood that a good yield is 400lb. (5 maunds) per acre, and that economical working is to grow this quantity for Rs. 50 per annum, and to pluck it, dry it, pack and deliver it on boardship at Colombo for 27½ cents. per lb.

(*N. B.*—High cultivation such as manuring is not provided for. This of course must be made to pay for itself in additional yield, which no doubt it will where the cost of transport is not prohibitive).

On this scale 400lb. of tea costs Rs. 160, or 40 cents. per lb. delivered on boardship. Recent London account sales of Ceylon teas have shown the charges (with freight at 45*s.*) to be within 8 cents. per lb. Let us allow 10 cents. The tea has then cost 50 cents. per lb. delivered to the buyer, who in the present state of the market pays about 1*s.* 4*d.* sterling for it. At the exchange of 1*s.* 9*d.* per rupee (allowing for the 10 cents. charges payable in sterling) this is worth 75 cents., which leaves a profit to the grower of 25 cents. per lb. or Rs. 100 per acre. The estate may be supposed to have cost Rs. 300 per acre to bring into full bearing, and we have the handsome return of 33 per cent. on the capital.

The figures upon which the above calculations are based have been carefully computed either from the usual Indian tasks being worked out in Ceylon money or from known local rates, and if of sufficient public interest, any detail can be explained or verified. Superintendence at Rs. 15 per acre is provided, so if the planter manages his own estate he gets that as income as well.

The value of 1*s.* 4*d.* per lb. in London is warranted by actual valuation and sales. An unsorted sample grown in the neighbourhood of Kitoolgalla and Yattiantotte (Yacdessa district) made by a native on Rs. 20 per month, the superintendent having no previous experience, was valued at 1s. 3¾*d.* Windsor Forest Pekoe Souchong recently sold at 1s 4*d.* Two or three years ago such teas would have been well worth 1*s.* 10*d.* to 2*s.*, and should the market recover, as it seems very probable it may, good estates will be worth Rs. 1,200 an acre.

The yield of 400lb. owing to the youth of the enterprise, has not been so widely verified by the present writer as to render this calculation *perfectly* satisfactory, but planters may judge for themselves what may be done when they know that double and more than double that yield is often procured in India under favourable conditions. (Some of our readers may probably have definite information as to yield per acre which we should be very glad to know). From observations which are now being made, there is reason to believe that the trees on an acre of coffee shed considerably more than 400lb. of dried leaf per annum, in addition to their yield of crop and husk.

The following table, which is calculated upon the basis above described, may be found useful, *viz* :—

A yield of	300 lb.	per acre gives Rs.	62 50	profit per acre.

Colombo, 21st Nov. 1879. S.

COFFEE.

FROM a communication addressed to the Commissioner of the Nilgiris, by Mr. W. S. Mullaly, it appears that the insect which causes the coffee leaf disease, or that is the result of it, has shown itself on the cinchona plants in the Droog Coffee Estate, may not this be another proof of the correctness of our hypothesis, that these diseases are caused by the abnormal treatment we give to these plants, treatment rendered necessary by the requirements of trade. It could never have been the natural habit of this plant to have its bark removed in the wholesale fashion which we follow, and may not the violent efforts which the roots are called upon to make, in order to recuperate the plant after the spoliation of its bark, be the cause of this disease. These diseases do not attack plants in their natural habitat, and while growing as Nature evidently intended them to grow.

FROM the *Straits Times* we learn :—The coffee crop of the Government estates appears to have considerably exceeded the estimate in Mid. Java. The crop in Kadu was estimated at 57,500 piculs, but 90,000 piculs have been received at the storehouses. The residency of Samarang was to produce by estimate 47,000 piculs, but the actual yield was between 60 and 65,000 piculs. Should this be the case everywhere in Java, the deficit in the Netherlands Indian estimates for 1880 will be easily remedied.

COFFEE AND CINNAMON IN NETHERLANDS INDIA.

(From the *Straits Times*, Oct. 31.)

"PADANG, 7th October.—We are informed that a couple of days after the last Government coffee auction here had terminated, four delayed telegrams were received by traders containing orders to purchase highland coffee at a limit of 62 guilders per picul. Had these telegrams been received in time, the stock of 25,600 piculs highland coffee sold at an average of 58·92 guilders per picul, would have yielded 50,000 guilders more, and the other descriptions of coffee offered for sale would have proportionately risen in price. Repeatedly have we and other persons pointed out especially the uncertain condition of telegraphic communication, and have urged improvement but always in vain. May we now hope that the considerable loss here alluded to will effect what years of complaints and representations have been insufficient to accomplish?"—*Sumatra Courant.*

The Padang *Handelsblad* states that orders had been issued to root out the cinnamon trees planted in the Government plantation on the west coast of Sumatra as shade for coffee from it having been ascertained that they are injurious to the coffee plants.

By the last accounts, the Sultan of Siak was at Batavia on a visit to the Governor-General of Netherlands India. A correspondent of the *Java Bode* writing from Bangkalis on the East Coast of Sumatra states :—

"It is reported that the voyage of the Sultan of Siak to the chief town of Netherlands India, has for object to testify his gratitude to the Government for the help and protection afforded him when his kingdom was threatened by Wilson, the English freebooter, and, what is probably the main object, to persuade the Government to grant him 200,000 guilders in return for certain concessions regarding his dependent states."

COFFEE IN MANILA.

"*Coffee.*—We have very satisfactory intelligence regarding the coffee plantations which have been established in several provinces in these islands, in consequence of the steps taken by H. E. General Moriones, the Governor-General, in favour of the development of this cultivation. According to very accurate information there are now four millions of coffee plants in the Phillippines, which may ensure a very considerable yield in a few years, and consequently an increase of wealth at which we rejoice in every way."—

Senor Sotomayor, a very wealthy capitalist, arrived at Manila on the 1st October, accompanied by a French engineer, with the object of finding employment in the Phillippines for capital amounting to several millions of dollars, on behalf of a company of Spanish and foreign bankers and capitalists. In commenting on his arrival, the *Comercio* says :—

"The Phillippines have a fertile and productive soil, and although the labour question is here the most formidable obstacle which stands in the way of industrial enterprise, it appears to us that want of capital is the reason why enterprises do not attain the prosperity desired, but mostly languish and die before becoming fully developed. Such being our opinion, we venture to assert that capital large enough to overcome every obstacle cannot fail to obtain that profit which, in the Phillippines, only awaits this magic rob to cause it to flow out as if by enchantment. Hence we

cordially welcome Senor Sotomayor, and we believe that we are not mistaken in stating that such are also the sentiments of men of business and the public generally here."

Coffee and Sugar.—Advices from Batangas state that the coffee crop this year which has begun to be collected is abundant, such as had never before been known there. Friends who have come from the provinces of Pampanga and Batangas inform us that the sugarcane plantations were in a most satisfactory condition, the cultivators expecting an overflowing crop."—*Diario.*

THE COMING BRAZIL CROP.

We are indebted to Mr. Pauncefote, formerly of this city, and now a partner in Messrs. Corrie & Co., London, for the following interesting return, which will be appreciated by Ceylon planters. The figures shew conclusively that the supply of coffee is likely to be considerably below the demand during 1880, there ought to be a continuance of high, if not higher prices.—Ed., *Ceylon Observer.*

Statistics of Rio Janeiro and Santos Coffee.

From 1st July 1878 to 30th June 1879.

Shipments.

Destination.	First 3 months.	Last 9 months.	Total.
States ...	482,230 bags.	1,776,170 bags.	2,258,400 bags.
Europe ...	601,460 ,,	1,736,340 ,,	2,337,800 ,,

Monthly average.

States ...	188,200 bags.
Europe ...	194,817 ,,

In first 3 months of Season 1879-80 :—

States took ... 715,125 bags }
Europe took... 409,981 ,, } 1,125,100

Prospective supply 1879-80 :—

	Old crop.	New crop.	Total.
Rio de Janeiro	900,000	2,500,000	3,400,000 bags.
Santos ...	—	1,150,000	1,150,000 ,,
			4,550,000 ,,
Deduct quantity to be carried over, say about ...			200,000 ,,
Leaves available			4,350,000 ,,
Deduct sundry shipments			170,000 ,,
Leaves available for Europe and States ...			4,180,000 ,,

Assuming States or Europe will require 1,700,000 bags in last 9 months, only 1,350,000 will be available for the other, and if States want coffee at same rate as for first 3 months, or 238,000 bags per month, where is it to come from?

Some authorities give available for shipment from Rio, crop year

1879-80	2,900,000
Santos	1,100,000
Total .	4,000,000
Of which already shipped	1,125,000
Available for 9 months	2,875,000

Or but 320,000 per month

Corrie & Co.

CINCHONA.

The Report on the cinchona plantation on the Nilgiris for the year 1878-79, has been issued, and shows continued progress. The total crop was 1,14,321lb., of which 1,03,444lb. were sent to London for sale. This latter realised a total of Rs. 3,79,789-11-5, being an average of Rs. 3·12·3 per lb., a very good average indeed. Extensive experiments are now being carried out, in order to test the comparative values of the mossing and coppicing systems, and we are promised the results in future reports. The total number of trees on these plantations is 1,10,889. The report speaks hopefully of the future of this industry, as we said before, it is now perhaps time that Government should dispose of their cinchona properties to private traders, they having established the industry as a paying concern.

CINCHONA CULTIVATION IN JAVA.

For the following translation of the Dutch Report we are indebted to the Straits *Times* :—

"Report on the Government Cinchona culture for the third quarter of 1879:—In this quarter also the weather continued rainy, so that only a few dry days were registered. Cropping has thereby been continually impeded, but the growth of the plants has been greatly promoted. To-day labourers, 1,843·20 guilders have been paid. The supply of labour is still short, so that the upkeep of the older plantations has had to suffer somewhat from it. Available energy has been utilized however for keeping the younger plantations clean. The very abundant rice and coffee crops have dispensed much money amongst the people and the inclination to work in the high mountainous districts is in inverse proportion to this wealth. Also the transport of collected bark has been retarded by want of labourers. During this quarter 26,123 Amstm. lb. of bark have been despatched. On the 2nd July 1879 the second portion of the 1878 crop—40 cases and 114 bales of cinchona bark—was offered for sale at Amsterdam, the average price brought being 209 guilder cents. per half kilogramme (the highest average was 560 cents. per half kilo.* for C. Ledgeriana)

THE PREPARATION OF CINCHONA BARK.

Messrs. Rucker and Bencraft, the London Brokers write as follows :—

Fine stem quill bark is generally bought by the druggists, the price is often, if not always, far above what the analysis would point to, or what a manufacturer could afford to pay. Such parcels are keenly competed for, the appearance of the bark being greatly appreciated by a portion of the trade. The length of fine stem quill bark should certainly not be less than a foot, we have seen fine specimens varying from two to there feet, and occasionally even still longer. The bark should be cut evenly and regularly, and it must never be sent to market flat, as we so often see the South American barks, but curled, as close and compact as possible. In all other cases, appearance, within reasonable limits, is not nearly of such importance as analysis. The branch barks would not be valuable so much on account of their appearance, but rather on account of their extracts. An even looking parcel is always slightly more attractive, than an uneven one, but the advantage gained in price would be almost infinitesimal. A most important matter, and one to which we wish especially to attract the attention of our Ceylon friends, is that the bark should be properly and thoroughly dried before packing. Bark ought to be so dry, that it is almost brittle, but never burnt or charred. The fine long quill barks should be packed in cases which are perfectly dry, but if other means are used to still further protect the bark, such as thick paper linings, varnish, or tarred, it must be remembered that such advantages are more than useless, if the bark becomes in any way contaminated by these preparations. The quills must be packed carefully and closely, the fine long quill barks are naturally brittle, and as their values depend so much on their appearance, every endeavour should be made to bring them to market long, strong, and handsome. For all other descriptions bags are generally used. We recommend the bags made in M... and called Thomas Brigg's Patent Baggage. Messrs. S... B... our largest importers of South American Barks, use this baggage almost exclusively. We can easily procure small pieces of this Patent for any of our friends, and as we have shown a specimen to Messrs. Howard & Sons, we can state that this package meets with their warm approbation. Damage by sea water, fresh water, or damp has a most injurious effect on Bark. Sea damage is bad enough, but when a parcel gets damage in the country and afterwards sweats in an almost waterproof and air tight package, the effect is ruinous. The following is most important, and should be written in red ink to attract attention:—To analyze a sample of bark properly, about five days are necessary. The chemicals used are very expensive, and we believe we are correct when we state that something like 32 processes have to be gone through. It is, therefore, evident that it takes a good deal of time, labour, and money to test a sample of cinchona. Small lots, deplorable as they are in most trades, are almost fatal in the bark trade. No manufacturer will take the trouble to test them, and we heard only to-day on the very best authority, of a case where a small lot, knocked down at sale for somewhere about two shillings, proved on analysis afterwards to be a most valued specimen, and worth many shillings a lb. more money. A Sale Lot should not contain, under any circumstances, a smaller quantity than 5 cwt. In the Sale Room this is the smallest quantity that gets fair attention. Larger lots sell still better, as more manufacturers test them, and thus more competition results. No package should weigh less than 100lb. and where possible, there should be at least 6 such packages in one Sale Lot. For a general rule it may be taken, the larger the bulk the better the price. Of course there is always the question of demand and supply, but on any given day, a large shipment invariably sells better than a small one. We note down the following remarks shortly :—

1.—Scrapings are best kept separate, we often call them twigs, as they are composed of small twigs and scrapings of white part of the tree; the larger the quantity, the better the sale.

2.—Ordinary quills may be mixed without reference to length, as they are valuable for their chemical properties, and not on account of their appearance.

3.—Large straight quills, of good colour, are bought by druggists at home and abroad, and generally at prices much above their value to manufacturers. It is important, therefore, that they should be packed carefully—they travel best in cases. All other sorts sell equally well in any package, as long as they come to market in a merchantable condition. The grower need only consider cheapness in package, and transit; bags and bales are most used.

* About 9s. per lb.—Ed., *Ceylon Observer.*

4.—If the parcel is large enough to do so without making the lots too small, the bark is best separated as follows :—

A Large Quills, B. Broken Pieces, C. Branch Bark, D. Roots if the trees are stubbed up. E. Twigy Bark &c., all that which when dry is less than the thickness of a quill, B. C. & D. can be mixed if the parcel is not large enough to give at least 5 cwt. to 6 cwt. of each; but the very small twiggy bark should always be sent separate, as it is worthless to manufacturers, and is only bought by druggists.

5.—Drying in the sun is said to be injurious, but it is most important that the bark should be dried thoroughly somehow or other. If not dry, [illegible] mould, rot, &c., &c., follow. We believe artificial heat is [illegible] satisfactory, in some form of drying-room or stove, but these [illegible] abused are fatal, as the bark will show signs of charring, burning &c.

At a recent sale East Indian Cinchona sold at irregular, but rather dearer prices.

SILK

[illegible] Switzerland [illegible] principally [illegible] Zurich [illegible] of Bale [illegible] occupy 2[illegible],000 [illegible] produce [illegible] total value of from [illegible] of francs. Its [illegible] manufacturing industry centres [illegible] Bale [illegible] the manufacture of silk ribbons [illegible] repeal of the edict of Nantes, by French [illegible] of which the descendants form to-day a part of the noble family of the [illegible].

In 1810 the canton of Bâle had from 500 to 600 looms of silk ribbons of different kinds, plain or brocaded and [illegible], which the quantity produced was to the value of [illegible] million francs. About 1830, these figures had [illegible] in 1872 that the silk manufacture of Bâle attained [illegible] total production in Switzerland, of [illegible] millions fra[illegible] alone made upwards of 60 millions. About [illegible] number of power-looms for ribbons amounted to [illegible]

	Looms
For Bâle town and district [illegible]	[illegible]
For the other cantons of Switzerland	1,[illegible]
[illegible]	[illegible]

It is estimated that the 7,562 looms of Bâle employ about 6,000 workpeople, of both sexes, in the town and its suburbs, and 60 designers and others. They consume annually 300,000 kilogrammes of conditioned silk, and produce 12[illegible] million yards of ribbons. From recent statistics, published on the occasion of a new federal [illegible] labour in the factories, the silk industry of Bâle only manufactured in 1877 a total value of 45 million francs.

[illegible] MANUFACTURE IN ENGLAND.

THE most beautiful of [illegible] materials used for [illegible] it displays to the best advantage the art [illegible] preparatory processes are also the most simple required by any of the textile substances, and as it is desirable to show the process of spinning, upon which in a great measure the beauty and quality of all cloth depends, the throwing of silk is, as in the case of weaving, therefore selected. Automatic spinning machinery was applied to silk long before it was invented for cotton, the former substance being, in consequence of the great length of its filaments, more adapted for the purpose, and the carding and combing processes, excepting for *waste* silk, are not required.

Mention is made of the silk manufacture in England so early as the year 1363, in an Act of Parliament passed in the reign of Edward III., but it was then of very slight importance. In France it was not introduced for more than a century later; but during the 16th century the mulberry-tree was extensively cultivated there, and the manufacture of silk was encouraged to such an extent that titles of nobility were conferred upon some manufacturers who had persevered and had been successful in the business. James I. of England observed that the French were deriving great benefit from this comparatively new manufacture, so he determined to encourage the trade in England. For this purpose he sent letters to all parts of the country recommending the people to cultivate the mulberry tree, and it became fashionable to do so. Thus it is related of Shakespeare, Milton, and others having planted trees of that description. The king also by a like proceeding requested his subjects in the American colonies to cultivate the mulberry-tree instead of that "detested weed" tobacco. He encouraged Mr. Burlamach, a London merchant, to introduce throwsters, and dyers from the continent, and in 1629 they became of such importance that the throwsters formed themselves into a company under the name of "The Master, Wardens, Assistants, and Commonalty of Silk Throwsters." In 1661 they are said to have increased to such an extent in London that 40,000 men, women, and children were employed in the business. But this statement, although mentioned in the preamble of an Act of Parliament, is probably very far from being correct.

Although the cultivation of the mulberry-tree was encouraged, it does not appear from that time to the present, that the production of silk has [illegible] been [illegible] England attended with any degree of success. The raw [illegible] the [illegible] upon which the manufacture depends, is procured from [illegible] favourable for its production, and large quantities are [illegible] Italy, India, China, and Japan. Before silk-throwing became [illegible] understood in England, the silk imported, at that time from Italy, came abroad thrown or spun. At first the English throwster could only spin "tram" [illegible] the most simple process of spinning as required for weft. The "organzine" used for the warp was for a long time afterwards imported ready thrown.

In 1702 a gentleman named Crotchet thought he saw a good opening for profitable speculation; he, therefore, erected a small silk mill at Derby, but he did not succeed, and he became insolvent. Some time afterwards Mr. John Lombe, who was a good draughtsman, went to Italy to obtain the secret of the process, and he succeeded in doing so by corrupting the work-people at one of the Italian mills. His plans were discovered and he had great difficulty in making his escape.

On arriving in England he fixed upon Derby where to commence the [illegible] and rented from the Corporation of that town a small island [illegible] by the river Derwent where he built a new mill adjoining the one [illegible] by Mr. Crotchet. During the building of the mill he obtained [illegible] of the Town Hall, in which he carried on the process under protection of a patent obtained in 1717, with such great success that it is said the [illegible] mill was gradually built and filled with machinery from the profits derived from the work done in the Town Hall!

In three or four years after he had obtained his patent John Lombe died when the proprietorship devolved on his brother William, and subsequently to his cousin Thomas, who afterwards became Sir Thomas Lombe, and who obtained £14,000 from the Government in lieu of an extension of the patent. Hutton says that the Lombes has amassed £80,000 before the expiration of the patent.

One of the conditions the Government exacted for the payment to Sir Thomas was that he should deposit in the Tower of London—perhaps the only available public place at that time—a complete set of models for the [illegible] machine, showing the process used by [illegible]. These models, some [illegible] forty years ago, were destroyed by the order of the then Governor of the Tower. Three or four pieces remain, however, and are to be seen in the Patent Office Museum. They consist of a spindle belonging to the throwing mill, a reel, and a portion of a "sledging bench," or the rail.

There is a tradition that John Lombe was followed by a woman from Italy, and that his death was attributed to poison administered by her in revenge for his obtaining, surreptitiously, the secret Italian process of throwing.

The Derby silk mill was long afterwards considered a great wonder, although in reality the process was exceedingly simple, for it was in the combination of the numerous spindles into each machine that really formed the value of the new introduction. A second mill was shortly afterwards built at Stockport, and from that time Congleton, Macclesfield, and Leek followed the example.—*History and Principles of Weaving. By Alfred Barlow.—Japan Weekly Mail.*

TOBACCO.

AS the cultivation of tobacco is coming well to the front of late, we will devote more attention to it than formerly, and will be at all times ready to give due prominence to such new products, or at least such products as are new to India, bearing on the agricultural and commercial prosperity of the country. As many of the Government experiments are being carried on with a view to the elucidation of all that it is desirable to know in connection with these new products, we have introduced a new heading, and under the title of "official papers" we will from time to time reproduce such of these documents as we may deem interesting to our readers.

HARVESTING TOBACCO.

A VERY good way is to cut the plants just at night, and take them to the shed early next morning after the "dew is off." The plants are then cool and less liable to pale rot or sweat by adopting this method of harvesting. In hanging the plants avoid crowding, as space is as much an object with tobacco growers as with newspaper men, and if the plants are over-crowded, the leaves are apt to sweat and rot. In about two weeks, however, the danger is passed and the leaves will have commenced to "cure down," changing first from green to yellow and from yellow to brown, the natural color of the leaf. Too rapid curing is not desirable, since the leaf is apt to be dry and husky, rather than soft and silky. Keep the sheds as dark as possible if dark colored leaf is sought for, and open the doors if a lighter shade is wished for. Close the doors next to the sun at all times, and open on the other side, but open all during the night, unless the weather is very muggy—a most dangerous time for the curing process and the time when pole rot and sweat will ensue. After the plants or leaves are all "cured down," close the sheds tight so that the color may even up, but should a damp spell come on, open the doors, but not if the rain beats in on the leaves. Before cutting the plants see that all are thoroughly suckered, as the offshoots are liable to grow when hung up and the curing leaves coming in contact with them are apt to rot and be otherwise injured. Tobacco plants may be hung up either with twine or string on lathes as may be thought best. Both modes of hanging in the sheds have their advocates, many claiming that when hung on laths the leaves cure better and are less liable to sweat or rot. Well-ripened tobacco will cure faster than when only partially ripe; hence there is less danger from rotting when the plant is thoroughly matured. Havana seed tobacco must not be cut unless well-ripened, as the leaves will be bitter in flavor if cut when green. The plants of this variety should stand in the field so long as there is no danger of frosts, say from eighteen to twenty-four days after being topped, and in some cases even longer. On low grounds, where the early frost nips the vegetation, the plants should be carefully watched and cut, even if not ripe; since a severe frost, or any frost, even a "white" one, unfits the leaves for use, and since unripe tobacco is better than that touched by this merciless foe of the weed—*Scientific Farmer.*

TOBACCO CULTIVATION AND MANUFACTURE.

THE weather is now all that can be wished for, and no time should be lost, for one genial shower of rain is worth more to the plant bed than half a dozen waterings. 1st—Plough or dig the ground at least 12 inches deep, break all the clods or lumps of clay as fine as possible, and work in a good quantity of wood or vegetable ashes. I would prefer that the seed bed be six inches higher than the ground, so that the plants or seed may not be injured by excessive rain, and I would advise that the seed be sown in drills, not broadcast, for this reason; if you sow in drills, you can the more easily weed, water and pull the plants, without trampling on them. Your seed bed can be a part of the tobacco field, and a piece of ground 30 × 60 feet, will give you sufficient plants for several acres. Do not sow your seed too thickly. Any fairly good ground will suit for tobacco. I would prefer it a little sandy; you can always manure poor land, whereas, if it be too rich, the plants and tobacco will grow too thick and rank, and not be suitable for cigar making. In America, a good loose sandy soil is always preferred. As soon as the seed is sown, the planter should at once plough the ground for tobacco as deeply as possible, and let it be so for at least two weeks, so that it be subject to atmospheric influence, when it will be more easily pulverised, it should then be harrowed once or twice, before the second ploughing. If you have no harrow, you can improvise one by using a branch of tree, on which you can tie some large stones. If procurable, use the seed known as the "James River." I believe it can be got from the Secretary of the Horticultural Gardens, but I would strongly recommend the planter not to sow seed of his own raising. In England and America no farmer will sow his own seed, but rather that from a farm some miles distant. By no means water your plants in the morning, but after the meridian sun has passed. If you water the bed in the morning, your ground becomes hard and the water will evaporate, whereas if you water in the evening, the water has a chance to percolate to the roots of your plants. Neither water too much. You do not require to flood your plant bed; moderate watering is always the best. When your plants are one inch high, it will be well to scatter lightly, with the hand, wood ashes over them, as this will in a great measure keep away the fly and the bug. If the fly should appear, it would be well to water twice a week with a solution of six parts water, one of wood ashes, and one part lime; this will destroy the eggs, and not injure the plants in the least. When about three inches high, your plants will be ready for setting out. Always select the strongest as you thin out the plants; they will grow rapid, so you will be able to plant out every two or three days. It would be well to have some mats at hand, so that you can cover your plant bed during the heat of the day. Your planters should bear in mind that the more care and attention they bestow on the plant bed now, the better will be their prospects for a good crop of tobacco hereafter. While seed is growing, it will take all the planter's time to get his ground into proper order to receive the plants, and he should be collecting all the refuse matter he can to burn and scatter over the ground previous to his second ploughing; burnt wood or vegetable ashes is considered about the best manure for tobacco, which requires a considerable amount of salt to be in the ground, else it will not burn, or if it burns, the ashes will be black. In the first place you should select your leaf tobacco with care, and to do so, you must exercise the senses of sight, feeling, smell, and taste. Select a thin, sound leaf, for the wrapper or outer cover; try and get the leaf so that the wrapper can be cut from *between* the veins, and not across; the inside or filler should be a light, or what is called trashy tobacco; this tobacco is much more free from oil, or nicotine, than is a heavy thick leaf. See that your leaf tobacco is evenly cured and of an uniform color, and before purchasing, try it, and see that it burns to a white ash and fragrant smell. The night before the tobacco is to be worked, see that the tobacco, selected for the wrapper is thoroughly moistened with soft water (it would be better to boil the water and let it cool) then roll it in a blanket or large coarse cloth; by this means the wrapper becomes pliable and will not tear. See that your workmen do not wet the fillers too much, for in this lies the great fault with your Indian made cigars. As soon as your day's work is ended and cigars counted, they ought to be spread in the sun for three or four hours and then cooled in the shade. Then you can pack them away in a large box, but if you tie up your cigars in bundles as soon as made, the damp filler and wrappers cannot dry, and the consequence is the filler becomes mouldy and ferments, thereby giving the cigar a bitter taste, and causing an unpleasant sound, like unto that of a wet or dirty pipe. Drying your cigars gives you another advantage, for you can place them in the market within a week and they will have an appearance of age, and smoke well. Now, sir, your Indian cigar-makers, as a rule, do not use the scrap tobacco (or clipping) but sell it to snuff-makers, at a nominal price, but in America this is all used as fillers, and I believe it makes a better cigar, than that made altogether of long tobacco.

I have no hesitation in saying that Indian grown tobacco, if properly *cured*, is as good as any grown in America; for you can use nearly all the tobacco raised in India for cigar-making, whilst in America, the States only of "Maryland, Connecticut, Delaware, and Florid," are capable of growing tobacco suitable for cigar fillers, and they are obliged to purchase Cuban tobacco for wrappers.—*Madras Athenæum.*

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

CORRESPONDENCE.

COFFEE MANURING: AN ATMOSPHERIC SUPPLY OF AVAILABLE NITROGEN.—ANALYSIS OF "CINCHONA SUCCIRUBRA."

To the Editor of the Ceylon Observer.

190, Kollupitya-road, December 6, 1879.

SIR,—The sanguine hope of M. Ville, that advanced agriculture, will yet be able to draw all the nitrogen required for plant food, from the atmosphere, lends a new interest to a subject touched upon in my last, *viz.*, may not the secret of the lessened importance of the more active forms of nitrogen in our manures, compared to what obtains in temperate countries be explained on the supposition that our atmospheric supply of available nitrogen is greater, either absolutely or relatively, to the products we have to cultivate. I am not aware if any tropical rains, dews, or atmosphere have been made the subject of exact analysis, so, in the absence of observed facts, it may be excusable to speculate a little on the subject.

There can be little doubt that the atmosphere is the primary source of the nitrogen in plants. The atmosphere is anterior to the soil in our cosmogony is in fact the great agent by which the soils have been produced, and nitrogen not being a constituent of the primary rocks must have been absorbed from the atmosphere in the first instance; ergo, all the nitrogen in plants comes directly or indirectly from the atmosphere; so in this sense Ville's expectation is present reality When one considers how important atmospheric combined nitrogen is to plants, this element constituting, according to Johnstone and Cameron, 1¼ per cent. of their weight, it is matter for wonder that it should be present in such small proportion in the air, and one would be *a priori* disposed to credit the conclusion which Ville early arrived from his experiments of 1849-1855 that plants can assimilat-ow. nitrogen; but English chemists are diametrically opposed to tktrogen It is so extremely difficult to estimate accurately the combime estima- in the air, that experimenters mostly confine themselvrished results tion of that in rain-water. Perhaps the most reliable— are those of Dr. Angus Smith who gives the follow-

RAIN-WATER IN PARTS PER MILLION.

Where collected.	Ammonia.	Albumenoid ammonia.	Nitric acid.
Ireland, Valencia	·13	·03	·37
Scotland, five sea-coast country places, West	·48	·1	·37
Scotland, eight sea-coast country places, East	·99	·11	·47
Scotland, twelve inland country places ..	·53	·04	·31
England, twelve inland country places ...	1 07	·11	·75

Calculating the averages we would get ammonia ·78, albumenoid ammonia ·08, and nitric acid ·49, or a total of ·835 of combined nitrogen in one ... water is ·0361lb., and an acre contains 6,272,640 square inches. A rainfall of one inch therefore weighs 226,442lb. per acre, of which ·189lb. is nitrogen. A rainfall of 30 inches per annum would only supply 5·67lb. of nitrogen per acre, a rainfall of 100 inches, like that of Ceylon, 18·9lb. Suppose we take a crop of potatoes at not less than 4 tons per acre, of which ·35 per cent. is nitrogen; 31·36lb. of nitrogen per acre would be carried away in a single crop of which the rainfall of the whole year could only supply 5·67lb.

Coffee contains much more nitrogen than the potato, *viz.*, 2·14 per cent not reckoning, for want of data, the parchment skin. A 5 cwt. crop nevertheless carries away only 12lb. of nitrogen while our rainfall of 100 inches as per Smith's analysis contains nearly 7lb. in excess of the demand for the crop. Mr. Horsfall assumes that 200 leaves are dropped per tree per annum. Mr. Fraser of Damboolagalla assumes 2,000;

we may assume that while 2,000 are dropped 200 are irrecoverably lost by wind and wash. This according to Mr. Hughes would remove other 6·6lb. of nitrogen per acre, still leaving a balance of ·4lb. to the credit of rainfall. If we knew what allowance to make for the parchment we should not have this balance; but in any case the result would be very different from a heavy crop like the potato which carried away 25·69lb. in excess of the calculated rain-supply. It is found, however, that the greater the rainfall the smaller is the percentage of nitrogen, *vide* table—east of Scotland has a smaller rainfall, but higher proportion of nitrogen than the west of Scotland, and dew has a much higher proportion than ordinary rain.

But there is still another most important factor to be taken into account. Boussingault found that when the atmosphere was in a highly electrical condition, the proportion of nitric acid in the rain was enormously increased. In ordinary circumstances he found only about ·02 per 100,000 parts; in a hailstorm, however, the atmosphere being highly electrical, the rain contained not less than 5·5 and the melted hail 8·3 parts of that acid (*Hassal*). Let us suppose the rain and hail together contained no more than 7; an inch of such rainfall (and thunderstorms of an inch of rainfall are not uncommon in Ceylon) would contain 15·85lb. of nitric acid, or rather more than 4lb. of nitrogen, and an inch and-a-half of such rain would contain more nitrogen than the whole annual rainfall of 30 inches calculated from Dr. Angus Smith's analysis.

I have been informed by a Colombo gentleman who has collected rain during thunderstorms in Colombo, that he has been surprised at the strong smell that was shortly developed in it. This odour could be of no other than nitrogenous origin. I think, therefore there is every reason to believe that the atmospheric supply of nitrogen to the plants in the tropics, is greater than in temperate countries, and when the soil is prepared to receive this nitrogen, it so far replaces the necessity for nitrogenous manure.

I meant to have said a word about the the fertilising power of gypsum in the soil being less, if at all, due to its power of fixing atmospheric ammonia than to other properties especially the liberation of potash; but my letter has already extended to sufficient length.

I conclude by handing you an analysis of cinchona succirubra I made the other day. The results are such to encourage planters:—

	per cent.
Moisture	... 11·67
Total Alkaloids	... 8·1
Quinine	... 1·8
Computed air dried crystalline Sulphate of Quinine,	2·42

M. COCHRAN, M.A., *Glasguensis.*

NOTE:—This has been kindly corrected and examined by Mr. Cochran for our use.—ED., *I. A.*

MONTCLAR'S SYSTEM.

SIR,—A plan suggested by Mons. Montclar to the coffee planters of Ceylon, is highly applicable to coffee and tea enterprise in India, I have the pleasure of sending to you for publication, the two articles which have appeared in the *Ceylon Times* on that subject.

A PROPRIETOR OF ESTATES.

THE MEDICAL DEPARTMENT AND THE COFFEE ENTERPRISE IN CEYLON.

I.

(*To the Editor of the Ceylon Times.*)

SIR,—When a man acts conscientiously and has the courage and frankness to state "that almost every stage in our coffee forced horticulture is on a wrong principle"—it is a startling assertion and one that, no doubt, sounds unpleasantly to many, who were regarded by the *Ceylon Observer* as model cultivators "far ahead" all over "the tropical world."

It is with such flattering assertions, as clearly pointed out in the *Ceylon Times* of the 25th October last, that the planting community has been induced to disregard the administrations of one who had come amongst us for the purpose of putting right, practically, our mistaken notions of coffee cultivation. But it is by the opinion and advice of thoroughly incompetent men that the planting community of a country may find itself "far ahead" in errors; even with cinchona the present "King!"

For our own interest let us by all means hear what he has to tell us, if we do not dare to see what he has to show us, not with microscopes but with crow-bars, pick-axes, &c.

As quotations can do no harm, I will quote from Monsieur Montclar:—

"In Ceylon, the planting community possess for their immigrant labor (which of course is not their property) its medical department, which costs about one rupee per acre per annum to the proprietors of estates. But as a great many coolies are unwilling to go to the district hospital, and prefer to be treated on the estate itself, by some empiric or by the Peri-dorai; it results that in extra medicines alone, many proprietors or superintendents of estates are put to the additional expenditure of another rupee per acre.

"Therefore, as far as my information is correct, we can put down two rupees per acre per annum for labourers' medical attendance and medicines.

"If for immigrant labourers the coffee proprietors of your colony are in the necessity of spending two rupees per acre per annum, for medicals attendance and medicines, it is strange to remark that since leaf disease has begun its ravage, it did not occur to the proprietors of very valueable estates to have done as much for their own immoveable property, *i.e.*, paying one or two rupees per acre, per annum, so as to have a permanent staff of scientific specialists under the direction of one head scientific agri-horticulturist of their own, so as to work out and put the coffee plantations in good and sound condition.

"Indeed with the liberal expenditure of £10 to £12 per acre per annum, as generally allowed for the last few years, your estates would have been put easily in good and sound condition, if the money had been properly expended.

"Proprietors of valuable estates should consider carefully this point, that it is much more difficult to treat a plant than to treat a man, or an animal. I cannot do better than reproduce here, for planters' careful consideration, what has been published by the *Ceylon Times* of 13th January 1879:—

"What physician called in to see a patient suffering from some external malady, would be content to treat that disease simply as an outward one; would he not rather first make inquiries and investigations regarding the previous life, and general bodily condition of the patient, and would he not try first to remove the cause, and to improve the general tone, in order that he might place himself in a position to overcome easily the so-called disease, which is probably but the outward evidence of internal and systematic mischief? So with the planter; if the coffee disease is to be effectually overcome, it will not be by looking at it with the eye of a mere *superficial observer*, but with that which sees deeper, and farther, as regards the matter in all its various aspects, and this can only be done by the scientific agriculturist.

"We must, in short, go to the source of the matter. It is utterly useless for planters to labour in the dark; they may go on manuring till doomsday, and the result will be not the manuring of the plant and the production of greater crops, but rather the manuring of the parasite and consequently, the encouragement of the fungus."

Now, let me compare what was stated in opposition to the above by the *Observer* on the 29th January last.

The *Observer* backing the life history of leaf-disease wrote:—"Just as the skilful physician diagnoses the disease as a preliminary to treatment, so Mr. Morris, as a preliminary to the account of the Wallah experiments, and as a guide to other experiments in the direction of a remedy, fully describes the nature, progress, and symptoms of leaf disease."

Is it possible to read a more monstrous statement than that Mr. Morris had "fully described the nature, progress, and symptoms of leaf disease" or that Mr. Morris has made "matured conclusions," &c.; when his belief from the very beginning was that "it matters little to us now how the coffee leaf disease came, and where it existed before it appeared in such force and spread with such rapidity among the coffee estates of Ceylon and Southern India."

Mr. Morris was introduced to the coffee world, by the *Observer*, as the greatest *savant* of our present age! and "Mr. Montclar's ignorance of the whole matter is so apparent, that it is almost descending to his level to notice him."

It is impossible for one man alone to adjust the several difficulties we meet with in the cultivation of coffee in Ceylon.

We have to alter the condition of the soil to receive renewed moisture, light, heat, and atmospheric action through it and to the roots in abundance; and with the aid of manure and stimulants used in the right direction, we shall no doubt strengthen the plant.

Mr. Hughes has made a great many analyses of soil, with what result Mr. Morris instead of studying the conditions of the coffee blossom, as a botanist, has fallen back on sulphur, and with what result is already known. Now, what can a mycologist do for planters?

Is it Dr. Trimen who can do what is desired?

Dr. Trimen will answer in the negative.

UNITAS SALUS NOSTRA.

II.

SIR,—In may last I quoted the words of Monsieur Montolar, allow me to quote further.

"My object is not to defend or criticise the old or new Medical Ordinance, but merely to make proprietors of valuable coffee estates understand, that their immoveable property is much more in danger in 1879, than in 1869 when leaf disease became apparent.

My object is to make them understand that the vegetable subjects on their property require medical attendance much more, at any rate as much as their immigrant labourers do, and to make them fully aware that it is what I had the honour of proposing to the planters of India and Ceylon in 1877.

It is a great misfortune that such proposal of *unitas*, so beneficial to the interest of proprietors at large, was not accepted and carried out at once.

Had my proposal, then, been carried out, not one estate in Ceylon would have been abandoned completely, as is the case now in 1879, causing losses to many.

Had my proposal been carried out, we should have been in a position to prove to capitalists that coffee trees can be invigorated and cured of the so-called leaf disease :—An estate of 300 acres of coffee, instance, should be divided into *two* portions of 150 acres each, so as to have one portion in a condition of bearing full crop, and the other one a small crop—and so on alternately every year.

Indeed, after a full crop, it is unreasonable to expect in your coffee-horticulture another successive full or good crop, because the roots and branches of the plant requiring pruning so as to renew the rootlets as well as branches, and manuring also required to strengthen them.

But the above to be effective requires of course a few weeks of hard work, and after a few months, this shows its effects before the blossom makes its appearance.

Therefore, it is clear that the portion of an estate so operated on cannot be ready to give a full crop that year. It is by the above mentioned division that we shall avoid the existing irregularity in the production of crop, by which irregularity both planters and capitalists are often discouraged.

That division will give time to the Superintendent of an estate to carry out the required operations alternatively every year on half of the estate, and such division is the means of regulating a yearly production by which capitalists will see clearly their way. The above will be obtained, and I guarantee it, if planters perform a complete system of cultivation.

But it is impossible to perform such a system on *steep lands*, as long as the rainfall escapes out of the land, and in that escape carries away the best soil, leaves, handlings, pruning, weeds, &c., to the ravines. If complete cultivation is carried out, as recommended and approved of by planters and others of experience, not only the leaf disease will disappear, but we shall have to moderate in some cases the foliage of the coffee tree, and in some cases its bearing. On that point I refer you to "the new coffee culture" which was published and advertized by the *Ceylon Times* on or about the 10th of January 1879, I refer you, in fact, to all what I have written in the *Ceylon Times* in the specification of my works, in the pamphlet on "soil diseases, &c."—about the true diseases of the coffee plant in Ceylon and India.

I have opposed Mr. Morris's system of sulphuring not jealously, as it was supposed by some persons, but by conscientious professional opposition, so as to avoid, if possible, great loss of time to planters by false hopes and expectations, knowing by long experience that one or two years' lost, in agriculture, is an irreparable disaster to many proprietors of estates.

In my conscientious endeavour I have failed even to be heard, I do not know when dispassionate consideration will allow me a fair and full hearing. My thanks are due to some impartial planters for having allowed me to show them what is the fundamental principle of my culture on steep lands, and it would have been of advantage to the planting community of this island, I think, if I had been allowed to prove my system fully.

To prove fully the above named great advantages, and prove particularly that the contiguity of the roots of your coffee plants should be obviated, so as to avoid further intermixture of the general infection, because the "root disease so alarmingly prevalent and fatal in some districts, and in some patches of every district" (*vide Ceylon Observer* of 31st January 1879), is due to the several causes explained by me already, and hence the ultimate death of the roots, and of course the death of the tree itself.

When the above points were to be secured at once, by one operation, and at a cost of Rs. 25 to 30 maximum per acre, as guaranteed by me, I am at a loss to understand how parties interested in the undertaking of coffee planting in Ceylon did not act in unity, so to allow a public trial on 100 or 200 acres of coffee, instead of rushing to sulphur, which is not a cure, and cannot be a cure in the case of the coffee plant. And believe me, had all the proprietors of estates paid one rupee per acre per annum, as suggested by me, the following would have been done since 1877, *viz*,

1st. Two experimental places of 100 acres each, in two different districts of Ceylon, would have been purchased, and full operations carried on.

2nd. A staff of five specialists engaged by me, for not less than five or six years.

After the cure of a plant, which has been affected by various causes, its vitality will tend to turn into too much foliage or too much bearing which of course, requires to be regulated, because the most important question is not merely the division of crop, but regulation in the production of the coffee trees.

They require to be regulated in the same manner that a good horseman regulates the proper speed of his animal, if he has to perform a very long journey. Indeed, if an imprudent horseman, having to perform a long journey of 1,000 miles, exhausts his animal before he has performed the first one hundred miles, it is almost certain then that horseman and horse will never reach their destination.

The case of the coffee tree in Ceylon and India, is exactly similar. Producers of coffee in Ceylon should endeavour to improve their production, and not let it go down, and not entirely turn their hope to cinchona the present 'King of the *Observer*, because it is far more probable that quinine will be before long produced artificially by chemists, than that caffeine will be."

Now, Mr. Editor, let parties engaged and interested in the coffee enterprize of Ceylon and India peruse carefully and dispassionately the above remarks and recommendations which I have quoted, and let them judge amongst themselves, if their valuable property (their estates,) does not require as much attention as their moveable labour (their coolies) and let them see if they can procure a better adviser and practical leader than the person I have referred to.

For our own interests, and before it is too late, let us consider this in

UNITAS SALUS NOSTRA.

CACAO IN NEW LAND.

(*To the Editor Ceylon Observer*).

DEAR SIR,—Cacao growers especially those who grow it in new land should endeavour to find a suitable and profitable product to grow in conjunction with it. Planted as it usually is, 12 feet by 12 feet, there is ample room to have some useful plant which might by its produce, for the time being, pay until the cacao came into bearing. After a very careful inquiry I have come to the conclusion that cacao in this country bears little or nothing until it is three years old, when if well advanced it *may* yield at the rate of 1 cwt of prepared cacao per acre. This it is generally deemed prudent to strip from the tree, to induce it to more firmly establish itself in size and dimensions, for the cacao, like a jac, sowersopp, or other tree-bearing fruit from *old wood* produces more or less respectively in accordance with the larger or smaller dimensions of the tree. Thus it is absolutely necessary if one wishes to have large crops at an early date, to adopt such methods as are most likely to enlarge and spread out the older and matured wood. Nothing will keep this back so much as early bearing. As a rule the finer fruit is on the oldest wood close to, if not growing actually upon the stem itself. Indeed it is very doubtful whether even a four years old crop is as advantageous to a proprietor as waiting until the 5th year, when fully 5 cwts, an acre in fair soil may be depended upon. With judicious treatment, at the 7th year the cacao estate has reached maturity, and its crop then will depend very much upon the treatment it has received and the resulting growths and extension of its branches. Well-developed trees may at that age produce very large crops indeed, while those which have been allowed to bear young often hang back, giving only small quantities of produce, disappointing in their outturn, and keeping back the full powers of the trees.

The West India method is to have other plants growing between cacao until the fifth year, when the land is usually given up to it alone.

In Ceylon, those who have planted it up largely, have usually quincunxed a Liberian coffee plant in between the cacao, which so far appears to be the best plant suited to the position. Even Arabian coffee should do well so situated in localities above 1,600 feet altitude, and if not planted too close, possibly having the cacao among it may have a beneficial effect upon leaf disease, most of such pests being the result of growing large unbroken expanses of one species of plant to the exclusion of others, for all experience so far goes to show that even should the germs of the *hemeleia* fall upon the cacao and adhere there, they would not grow, but eventually die. In this manner land planted up with two

products, one of them being coffee, would be far more likely to keep freer of leaf disease, than if growing coffee alone.

Having a useful plant growing between cacao trees would better enable the proprietor to sacrifice his first fruits of the cacaos until they had attained large and productive dimensions and would not injure them as their roots at that age would not have fully occupied the soil.

Another advantage of an alternative plant is, that if anything happens to the cacao, it is there to occupy its place. As far as my experience goes, I have no hesitation in saying that I have found Liberian coffee the best plant to grow between cacao, and as I have not the remotest fear of its failure in the European markets, having had the opinions of foreigners upon it, shall continue its cultivation steadily. Holland has now, as well as America, pronounced it superior in quality to the old Arabian kind, which superiority is simply that being stronger in flavour it bears more chicory. There is, too, every reason to believe that plants raised from locally grown seed will produce larger, stronger, and more productive trees, for those now growing in my nursery are darker in leaf, thicker in stem-and-what the original trees were not are free apparently from leaf disease.

PIONEER.

TROPICAL CULTURE.

TO THE EDITOR.

SIR,—The *Indian Agriculturist* being the special organ of tropical culture (both native and European), it is clear that all information published by such a paper is of the highest interest to those engaged in agricultural pursuits in the East. Indigo, coffee, tea, cinchona, are the chief Agri-Industrial undertakings in India, to which Europeans, in general in India, have devoted their attention, capital and energy when rice cultivation has been and will be, always, the grand general culture of the natives from Cape Comorin to Afghanistan.

Much having been said, already, about the principal cultivations undertaken by Europeans in Ceylon and India, I consider it fair and just that something should be stated in favour of the grand culture of rice—on which depends the 220,000,000 souls of the British Indian Empire.

For the Scientific-Agriculturist acquainted with the *barbarous* cultivation of rice in India, there is no doubt, whatever, that such culture can be improved very much, for the interest of the native cultivators as well as for the interest of the country at large, because rice when very cheap, means abundance, and abundance means no famine price but prosperity. Before proceeding to explain the new method of paddy culture I recommend, allow me to express a hope, in favour of humanity and progress, that my new method for paddy cultivation will not be opposed; as has been the new method of mine for planting coffee and tea on the lands on steep hillside of Ceylon and India.

When routine and ignorance oppose progress, it is *easy* by demonstration to convince routine and ignorance. Indeed nothing is more conclusive than much higher clear profits—and by them routine and ignorance disappear entirely to make room for progress, for still more improvements, which by degrees amount to these wonderful ameliorations we see in our days, of competition in every branch of Industry.

But when it is *too-much-intellect* which oppose a new improvement actuated by selfish interest and speculation, then it is a much more difficult matter to turn the stream of speculators who live on the inexperience of new comers in India and Ceylon.

This has been the fate of my new method in Ceylon and India, *i.e.*, powerful opposition so as to prevent new openings of coffee or tea on the principle recommended by me!

Of course if new comers to Ceylon and India were to invest their capital in making new openings, according to the last perfected agricultural method, *in preference* to investing in estates already washed away, and thus requiring expensive manuring and other indispensable operations, (so as to avoid further progressive wash of soil and manures) by which it is clear that the market value of existing estates will be disturbed.

That consequence has been the cause that strong opposition has been made against the Montclar method, and that the sulphur cure was advocated in opposition to the said Montclar method.

But that opposition has been a suicidal mistake for the interest of the *mortgagees* of coffee and tea estates, because it is clear as daylight, that a method having for special and principal object the prevention of soil, manures, &c., being *further* washed away, is a method able to improve and make no injury to any estate situated on steep lands, but in fact a method able to give by and by more value to existing estates. It is true that if some 200, or 100, or 50, or 25 tons, of humus per acre have been washed away already to the rivers or to the sea, the method Montclar will never bring them back! . . . But when there are many estates on which 100 or 50, or 25 tons of splendid arable soil, per acre, are still existing, is it not a calamity to allow them to be washed away?

Indeed it is a calamity, and a calamity due to the voracious and dishonest speculators who have, at last, been so well depicted by the Ceylon Press under the names of "Coffee Sharks"—and "Pilot Coffee Sharks."

Having been much disappointed and discouraged by the doings of the abovenamed "Sharks and Company" I beg to be allowed for the present to take leave of the coffee and tea planting questions in Ceylon and India, and devote my knowledge of tropical agriculture to the improvement of the grand culture of rice, from Cape Comorin to Afghanistan.

I.

The statement that—"The present system of native agriculture is both wasteful and barbarous" is indeed, perfectly correct. It is the very primitive system of agriculture which was carried out 3,000 years ago. The judicious and important remark:—"Wherever there is water stored and available, fifty per cent. of it is absolutely allowed to run to waste," deserves full consideration from the Government of India because wastage of stored water for irrigation purpose is a serious question. Now, the other points, as mentioned by me, being entirely agricultural, I have much pleasure to add some more information, to prove how "barbarous" the paddy culture, as carried on in India is.—

1. The native cultivator "keeps the terraces of his field from four to six inches under water, as otherwise weeds would grow apace and choke the paddy plants. It is, therefore, not because the paddy wants to be constantly supplied with water that the plants are allowed to stand with their feet in water until the corn begins to ripen, but simply to keep down the weed."

2. The above "to keep down the weeds"—is one of the causes of wastage in paddy culture. But another cause of wastage of water is the necessity of preventing the sheet of water becoming *hot*, or else the productive powers of the plant would be weakened.

3. But there is, still, another reason for wastage of water as much as possible, *viz*:—

(*a*) The native cultivator is not a scientific man, it is true, but he is a *good observer*, and he knows fully well, that the more he runs *renewed water* in his field, the better it is for his crop.

(*b*) He knows, not by *science* but by *experience*, that *running water* benefits his culture, when stagnant or insufficient water injures it. Knowing that, he therefore uses as much water as he can, and his so doing is, no doubt, disastrous (particularly in India) to a country dependent on irrigation for its general grain cultivation.

4. But notwithstanding such disastrous wastage of water, by keeping the terraces of his field from four to six inches under water, he precludes *air, light*, and *atmospheric action*, acting through the soil and on the roots of the paddy plants, which circumstance, alone, is an immense disadvantage for the production of crop.

In acting as he does, the native cultivator has three objects in view.

The first object is to prevent the growth of *weeds*, and thereby avoid weeding operations.

The second object is to moderate the *heat* of the water.

The third object is to give to the *roots* of the paddy plant, *the benefit* of the oxygen contained particularly in *running water*.

5. If for weeding operations, (which are made by children and women) the native cultivator was to allow 20 per cent. more in his actual labour, and he was taught to make use of capillary irrigation, as I propose, not only 50 per cent. of water at least, will be saved, but his crop in grain and in straw will be more than doubled.

Double crop in grain, double crop in straw, and 50 per cent. saved in water for irrigation purpose—*versus*—20 per cent. of additional labour for weeding operations, are things of interest, I suppose, to the Government and to the people of a country.

Paddy cultivators should be aware that by allowing free access to the soil and roots, of air, light, heat, atmospheric action, and sufficient water (not wasteful) by *capillary action*, the above highly satisfactory results will be obtained easily.

There is no doubt, that the above are considerations of the greatest importance the complete practicability of which I am prepared to prove experimentally to the people and Government of India.

Here what I shall have to contend with is, not the opposition of self-interested speculators, but simply the habit of routine of the generally uneducated native ryots, who are afraid to undertake any agricultural experiments, as failure might be their ruin.

It is evident, then, that in the case of the ryots, generally poor, it is the duty of a paternal Government to take the initiative.

Indeed the improvements suggested are absolutely necessary as a preliminary to the application of suitable manures and stimulants (natural or artificial.)

Under the present system of paddy cultivation, the soluble portion, the best part of the manure and soil, must be *dissolved* and carried off with the running water to be deposited elsewhere.

To avoid much of this disastrous waste, I propose to water the paddy plant by the capillary attraction of the soil (according to the degree of the capillary power of the said soil) by means of a system of small water channels; making provision for irrigating the whole surface of the field, *intermittently*, should the soil be deficient in capillary power.

It is impossible to demonstrate agriculture on paper, specially for a foreigner writing in English; and what I can do just now is to demonstrate on paper the principle on which my system is based as clearly as I can.

CATTLE MANURE AND MANURING.

Chemical Laboratory, 190, *Kollupitiya-road*, 26*th November* 1879.

DEAR SIR,—I read the letters of your two correspondents of 13th instant and your article of 25th, on cattle manure and the ashes of the same. I also read part III. of Mr. Caird's article in the *Nineteenth Century* " on India, the land and the people," where he gives the result of Mr. Robertson's interesting experiment with cattle manure in its natural and calcined conditions. We are of course bound to suppose that Mr. Robertson has furnished us with facts. All that we can strictly infer from this individual experiment is, that in the particular kind of light soil dealt with, and cultivating a green fodder crop such as cholum, the ashes of cattle manure are nearly equal in fertilising power to an equivalent of the manure in its natural state. From your remarks on box feeding of cattle at Saidapet, I take it for granted, that when Mr. Robertson, or rather Mr. Caird, mentions cattle dung, he means the total excrements solid and liquid. If this is so, the experiment referred to is farther evidence in favour of a considerable potash ingredient being desirable in our artificial manures. You are of course quite right in stating that the nitrogen of cattle manure has always been considered of paramount importance by writers on agricultural chemistry; thus the late Professor Anderson says :—" In the management of the dung heap, there are three things to be kept in view :—First to obtain a manure containing the largest possible amount of nitrogen; secondly, to convert that nitrogen more or less completely into ammonia; and thirdly to retain it effectually." As Anderson's remarks on the second and third heads bear so directly on the questions you have raised, and as I rather think his work is now out of print, I offer you his views in his own words, though the quotation is rather a long one. After speaking of the nitrogenous foods by which the manure is enriched, he says :—" Although it may be possible in this way to increase the quantity of nitrogen in the manure, there is a limit to its accumulation, due to the fact that it is contained most abundantly in the urine, which can only be retained by a sufficient supply of litter. When that is deficient, the dung heaps become too moist, and the fluid and most valuable part drained off, either to be lost, or to be collected in the liquid manure tank. In the well-managed manure heap, the quantity of litter should be sufficient to retain the greater part of the liquid manure, and to admit of only a small quantity draining from it which should be pump d up at intervals, so as to keep the whole in a proper state of moisture. Attention to this point is of great moment, and materially affects the fermentation. When it is too moist, or too dry, that process is equally checked in the former case by the exculusion of air which is essential to it; and in the latter by the want of water without which the air cannot act. The exact mode in which the manure is to be managed must greatly depend on whether the supply of litter is large or small. In the latter case the urine escapes and is collected in the liquid manure tank, and must be used by irrigation, and in some cases this mode of application has advantages, but in general, it is preferable to avoid it and have recourse to substances which increase the bulk of the heap, sufficiently to make it retain the whole of the liquid. For this purpose, clay, or still better, the vegetable refuse of the farm, such as weeds, ditch cleanings, leaves, and in short, any porous matters may be used. But by far the best substance, when it can be obtained, is dry peat, which not only absorbs the fluid, but fixes the ammonia, by converting it more or less into humate. . . . . Good peat will absorb about two per cent. of ammonia, and when dry will still retain from 1 to 1·5 per cent., or nearly twice as much as would be yielded by the whole nitrogen of an equal weight of farm yard manure. Peat charcoal has been recommended for the same purpose, but careful experiment has shown that it *does not absorb ammonia*, although it removes putrid odour, and though it may be usefully employed when it is wished to deodorize the manure heap, it must not be trusted to for fixing the ammonia.

' Much stress has been frequently laid on the advantage to be derived from the use of substances capable of combining chemically with the ammonia produced during the fermentation of dung; and gypsum, sulphate of iron, chloride of manganese, sulphate of magnesia, and sulphuric acid have been proposed for this purpose and have been used occasionally though not extensively. They all answer the purporse of *fixing* the ammonia, that is, of preventing its escape into the air; but the risk of loss in this way appears to have been much exaggerated, for a delicate test paper held over a manure heap is not affected; and during fermentation, humic acid is produced in such abundance, as to combine with the greater part of the ammonia. The real source of deterioration is the escape of the soluble matters in the drainings of the manure heap, which is not prevented by any of these substances, and where no means are taken to preserve or retain this portion, the loss is extremely large, and amounts under ordinary circumstances to from a third to a half of the whole value of the manure Manure, therefore, cannot be exposed to the weather without losing a proportion of its valuable matters depending on the quantity of rain that falls upon it. Hence it is obvious that great advantage must be derived, especially in rainy districts from covered manure pits. This plan has been introduced on some farms with good effect, but the expense and doubts as to the benefits derived from it have hitherto prevented the practice from becoming general. The principal difficulty experienced in the use of the covered dung pit is, that when the litter is abundant, the urine does not supply a sufficiency of moisture to promote the active fermentation of the dung, and it becomes necessary to pump water over it at intervals, but when this is properly done, the quantity of the manure is excellent.' Regarding the box feeding of cattle he says :—" Whatever objection may be taken to this system so far as the health of the animals is concerned, there is no doubt as to the complete economy of the manure, provided the quantity of litter used be sufficient to retain the whole of the liquid; but its advantage is entirely dependent on the possibility of fulfilling this condition."

In European agriculture the retention of the nitrogen is thus regarded of so much importance that the calcination of cattle manure for this reason alone (apart from its mechanical virtues) would never be thought of. But as we find in Ceylon that highly nitrogenous manures such as guano are avoided, it would seem that here the nitrogenous element in manures is not equally important, and conditions of soil and crop to be cultivated may in certain cases even justify the calcination of cattle manure to save carriage, though it would be well to be first satisfied that there was a fair percentage of nitrogen in the soil. It would be interesting to know if besides other climatic conditions, a greater abundance of ammonia in the tropical dews and rains has not much to do with the question. 'In Paris 1,000,000 parts of rain water contain 3·19 parts of ammonia At Rothamstead there is an average of 1 grain per 14 gallons. The atmospheric supply of ammonia is intimately connected with the storing of nitrogen in plants.' Some facts on this subject would form an interesting commentary on the Surveyor-General's returns of the rainfall of different localities.—*Ceylon Observer.*

M. COCHRAN.

THE PONDICHERRY ARTESIAN WELLS.

(*To the Editor of the Madras Mail.*)

SIR,—Having seen, in a local paper, the report to the Revenue Board of the Superintendent of the Geological Survey on the Pondicherry Artesian Wells, I shall be glad to make a few observations on a subject so worthy the attention of Engineers, and of those interested in finding water for irrigation or otherwise. The " gushing wells " existing in Pondicherry cannot reasonably be classed in the category of artesian wells, as their delivery is owing to the waters of the Ponear and Gingee rivers penetrating into the strata of the valley where these rivers run, and at a higher level than that of the spot where the wells have been bored. Such would probably be the case in the valleys of the Cuddalum, of the Vellaur, and of the Cauvery. Here it is necessary to record the opinions of Messrs. Degousée and Laurent, the latter an able geologist, partner of the former, who is so well-known for the large number of artesian wells bored in nearly every part of the world. They say :—

" *Artesian springs in the alluvium.*—The alluvial formation is composed similarly to the detritic one, by *debris* and fragments from strata and rocks; it differs from the detritic formation by a more regular stratification, the *debris* stratified having very often no analogy with the surrounding formations. The alluvial formations are generally composed of sands, gravels, rolled pebbles, marles, and clays; old deposits are found sometimes on elevated sites, covering an extensive tract of country. At the times when great currents were in existence on the surface of the earth, the then existing valleys were filled up by alluvial deposits, which could be seen now covered by rich vegetation and culture, and in the middle of which water runs more slowly than heretofore. The pervious nature of the alluvial strata allows the waters to penetrate undergound, and to follow a subterranean course, reaching tracts far from their original bed and, although concealed, the waters underground are submitted to the same variations as if they were above the earth. The springs are more frequent into the alluvial than into the detritic formation; in fact as the surfaces in the former are generally much extended, the waters could run very far into the permeable strata, which are often covered by impermeable ones. If there exist, at a long distance from the spot of the infiltration a place at a level lower, the water, owing to its tendency to equilibrium, will ascend into any boring made at such

place. The more important alluvial formations known are those of Holland, of the valley of the Rhine, and upon the shores of the Adriatic near Venice. In this salt locality, Mr. Pasini thinks that the thickness of the alluvial strata may be estimated at 400 metres. If one ascends the country from the sea up to the foot of the Appennines, he will observe that the country is composed of strata alternately pervious and impervious, that the first extends over a larger area, and absorbs a larger part of the water from the numerous streams which run across the country. It was from these observations that we concluded the certainty of successfully boring artesian wells into that alluvium (Guides Sondeur, by Degousee and Laurent, vol. I., page 322)."

Evidently this description of an alluvial valley, into which artesian springs may be successfully bored, is eminently adapted to the Ponear, Vellaur, and Cauvery valleys on this coast. The valley or basin of the Ponear in which Pondicherry is situated, is composed like the Venetian alluvium, of strata alternately permeable and impermeable. This valley extends over an area fifteen miles S. and N., and from the sea westwards, twenty-five or thirty miles. It has the form of a triangle, the basis of which is represented by the coast extending from Gunnimode, near Marcanum, to Cuddalore. These strata deepen eastwards at a very small angle and their outcrops could be seen westwards of Pondicherry. The waters of the Ponear valley penetrate the pervious strata of this valley, and follow an underground course, being confined between layers of impermeable substances. As the valley of the Ponear is rising westwards at the rate of two inches per mile, there is nothing to be surprised at, if, by boring at the lower part of this valley, the subterranean sheets of water will ascend and overflow the ground, if the boring made is conducted deep enough, and through the stratum superincumbent to the water. Such result is entirely in accordance with the theory of artesian wells. We do not admit that, in the Pondicherry wells, ascension of water is produced by the pressure of the superincumbent strata upon a volume of water confined. In behalf of my opinion, I will record the remark of F. Arago, on the same subject; he is certainly an authority on these matters. He says (Œuvre Completes de F. Arago, by Barrat, vol. VI., page 307).

"I will examine now a very odd hypothesis. The water sheet into which plunges the tube of an artesian well, is always confined between two mineralogic impervious strata. The one above supports the weight of the superincumbent strata, and this stratum, it was said, must of necessity sink, thus pressing down upon the water below; this, it is added is the sole reason of the water's ascension. Admitting for a moment such flexion existing, then there will be three cases to consider, *1st.* The stratum, giving way and sinking constantly, will reach a level lower and lower, till it comes in contact with the stratum underlying the water, *2nd.* Or that stratum will cease to sink, and will take a position of equilibrium, *3rd.* Or finally the stratum may have an oscillatory motion. But neither of these hypothesis could agree with the regularity of delivery observed in the artesian wells. With the 3rd hypothesis the delivery would be intermittent. With the 2nd, after having diminished little by little, the delivery will stop. With the first there would be sooner or later a cessation of delivery, particularly if the water sheet has a moderate thickness."

I have said that my opinion was that the waters of the Someicherry "wells" were those of the Ponear valley, and in proof of the probability of this, I can mention: *1st.* That the same "confervæ" which are found in the rivers of Ponear and Ariancoupan are carried under ground, and "gushed out" by the water of the artesian wells now flowing at Pondicherry, and are deposited upon the beds, and sides of the streams produced by the wells. *2nd.* That it has been observed, when any flood occurs in the river of the valley, the delivery at the wells is increasing. I should, therefore, conclude that the delivery of water by the Someickerry wells being produced by the head resulting from the difference of levels between the entrance into the ground and exit at the boring, such wells can be safely considered as "artesian wells."

There are now three wells at Pondicherry, on 56 metres deep, another 78 metres, and the last 85 metres. The borings made at these wells have shewn the existence of four different water sheets; since the beginning of the flow, the waters have had their delivery at the same rate. Now, as regards the idea which has led to the boring of artesian wells, I can say that by the examination of the country surrounding Pondicherry, and particularly from the alluvial nature of the valley, it was thought long ago, by geologists, that there was some chance of finding artesian water, by boring through that alluvium. I will say in passing that, to my knowledge, several borings were commenced in Pondicherry and neighbourhood, with that object in view. M. C. Poulain, however, is the first who has solved the difficulty. Before attempting his boring, he consulted all the available documents to elucidate the question, and was principally led to hope a successful result, by the perusal of Lieutenant, Newbold's pamphlet, by the report of Mr. Blanford (1862), and that of Messrs. Foote and W. King, (1864). Adopting the ideas of these gentlemen, M. C. Poulain, notwithstanding the opinions of several scientific persons of the locality, began his work, and was, after much difficulty owing to the need of proper tools and apparatus, fortunate enough to tap a water sheet overflowing his tube on the 9th September 1877. A few months after M. Poulain bored another well, and found an overflowing water sheet at 87 metres below. The success of these two wells opened the eyes of the most incredulous and the French authorities, acting upon M. Poulain's suggestions, entrusted their Chief, Engineer with the boring of a well at the Colonial Garden. This last boring traversed three different water sheets, artesian, one at 37 metres, another at 69·10, a third at 73·60, and the last at 79·56. From the quantity of the delivery of these three wells, I fancy that the water enters the bearing strata not far up in the valley. The hydrostatic pressure at these wells has been found to be about 1·80m. to 2 metres but the delivery is not in accordance with such head owing to the obstructions of the strata at the foot of the tube acting as a kind of filtering apparatus.

There are more artesian wells in process of execution at Pondicherry The most important is the one under boring by Government in the northern portion of the town. There the depth arrived at is 150 metres, without any "gushing water" having been obtained. It is to be supposed that the water bearing strata are dipping northwards. This seems to be confirmed by the geological theory which states that at the time a strong current was denuding that portion of the cretaceous formation which could be seen now near Valdaraur, this current had its exit on the sea near Marcanum, and it was then probable that the erosion of the tertiary formation at the foot of the Pondicherry red hills must have been very deep; and if such is the case, the alluvium must have a great thickness at the spot where the Government boring is being executed. In conclusion, I will say, it would be very important to have the Superintendent of the Geological Survey sent to examine the valley of the Ponear. His observations will have a great weight as regards the selection of sites for boring artesian wells, and this also could be said of the Vellaur valley and of the Delta of the Cauvery.

Yours, &c.,

A. DECLOSETS, C.E.

☞ Mr. King, of the Geological Survey has already started for Pondicherry to make inquiries regarding the Artesian wells.—ED. *Madras Mail.*

THE JACK FRUIT TREE.

SIR,—I am told by some natives that the jack tree (Artocarpus integrifolia) will not bear fruit if reared in a nursery and transplanted, or at any rate the fruit it bears will be of bad quality and sparce; these people say that the seed should be sown where the tree is intended to remain. Others, again, tell me it does not matter at all—can you tell me which is right? I find the young trees bear transplanting well and thrive.

INQUIRER.

BAMBOO FOR PAPER STOCK.

TO THE EDITOR.

SIR,—A correspondent, who it appears has followed the controversy between Dr. King and myself in your journal, somewhat quaintly illustrates the position by quoting the story of "The two Knights and the Shield," meaning that the question at issue may be regarded differently from different points of view.

Be this as it may, it is useless now further to discuss, whether the system of cropping bamboo followed by Dr. King which has resulted in failure was, or was not the system I recommended.

Agreeing then in the new departure taken by Dr. King in his last Annual Report, wherein he puts forth three questions for settlement, the 1st of which, *viz.*, the formation of plantations is now under the able direction of Dr. Ribbentrop, Conservator of Forests in British Burmah; the 2nd question to determine is, quoting Dr. King's own words "Whether "commercial success can be obtained by collecting the immature "shoots of wild bamboo in the Forests, and carrying them to a Paper "Factory." Dr. King's third question of a Floating Paper Stock Factory, need hardly be further referred to, as I have shewn *that*, to be impracticable.

Judging then from the results I have already recorded in your Journal, as realised in British Burmah, there can be little reason to doubt that where floating facilities exist which happily generally occurs where bamboos abound, the young season shoots can be delivered (floated upwards of 120 miles) for Rs. 15 per 1,000, each thousand when crushed and dried being more than sufficient to manufacture one ton

of paper stock; and I may add that I am credibly informed, that from other localities bamboos are procurable at much less than Rs. 15 per mille.

Due to the scarcity and high price of Esparto Grass, paper-makers are now paying from £6-10 to £7 per ton for the lowest quality; we are reduced to eke out our supplies of raw material, to use straw, which imported in large quantities from the continent now commands from 55 to 60 shillings per ton, therefore just double the cost of bamboo, far inferior, however, in quality to the latter, and not yielding one-half the quantity of paper-making fibre, so far therefore as regards the mere cost of raw material is concerned, there is ample margin, and as regards quality, I can merely repeat that bamboo as a paper-making material is as far superior to Esparto, as Esparto is to straw.

It must be noted, however, that as with Esparto and other raw vegetable products, there exists great variety of quality, so with bamboo, (General Munro indeed in his Monograph on the Bambusaceæ published by the Linnean Society, describes more then 170 varieties or species of bamboo) therefore in collecting the young season's shoots from the native forest, not only must proper selection be made of the variety of bamboo collected, but careful supervision be exercised as to their quality, age, stage of growth, and other necessary points of detail; some bamboos being far more suitable for paper-making material than others, but to their essential points, I will refer to in another letter, remaining, &c.

THOS. ROUTLEDGE.

WATTLES FOR TANNING.

(To the Editor of the Australasian.)

SIR,—Being anxious to collect some good seed, I am at a loss to know how to tell that which is the best. That black and golden varieties are he best I learn from the report of the Wattle Bark Commission, and while the broad long leaf enables the golden to be easily distinguished, nothing that I met with in the report enables me to distinguish the black from the silver or other varieties. I find that bark strippers are not at all agreed about the names of this tree. In my rambles I meet with a black bark, a green bark, a bark covered with white spots, rough and smooth barks—trees on creek banks, flats, and ranges. Excepting the golden the leaf in all appears to me alike. I have been told that a white flower distinguishes the silver wattle, and that the bark with which spots is silver wattle; but I observe this latter bearing a yellow flower, while the white flower I have not seen at all. Pertinent to the information I am seeking, does it matter whether the seed be taken from a young or an old tree, from the bank of a river or mountain side, or a tree with extensive or sparse blossom on it?

SCHOOLBOY.

The real black wattle, or true tanning variety, is the acacia delbata. The silver wattle, which is considered inferior to the black, is the acacia mollissima, which can be easily distinguished by the silvery appearance of the under part of the leaf, and the glaucous appearance of the bark; the flowers of the latter are a bright yellow, that of the former a dirty yellow. The silver wattle is in general found on the banks of creeks, the black wattle on high dry ground. The seed, so long as it is good, may be gathered from any tree.
—ED. *A.*]

KOTEGURH NOTES.

SIR,—The weather has been dry. A few flakes of snow fell on Christmas day, and though we cannot say we had a white Christmas, still we can say that snow fell on this festival in 1879. On the 27th and 28th snow fell, here and through not much in quantity, yet it will do good to the roots of all kinds of vegetation.

The following is a comparative table of the past five seasons:—

	1875.	1876.	1877.	1878.	1879.
Rainy days ..	2	1	5	0	0
Snowy days ..	1	0	2	0	3
	Snow at the beginning: dry during middle and to the end.	Dry.	Tolerably dry for the first three weeks: wet towards the end.	Very dry, wheat and barley stunted.	Dry during the first three weeks: slight snow, about 2 inches towards end.

Wind N. E. and N., the latter bringing down the snow. Atmosphere still continues very brilliant.

The thermometer (Fahtrenheit) hung in an open verandah W. aspect; averages 41° in the morning, 47° in the evening—highest 50°, lowest 35°. In the open air the thermometer is about 8 degrees lower during the night. Sun rises about 7-10 A.M., and sets (*i.e.*, its last rays depart from the peaks of the snowy range) about 4-45 P.M.

Subjoined is a comparative table of the averages of the past five years:—

	1875.	1876.	1877.	1878.	1879.
Wet days ..	93	91	91	82	94
Haily „ ..	3	5	10	11	9
Snowy „ ..	5	7	7	4	8
Days on which moisture fell..	101	103	108	97	111
	Dry spring, suitable for cereals, though unsuitable for tea. Wet towards end of year.	Dry spring: unsuitable for tea. End of year dry.	Wet spring, suitable for tea. Rainy season very moderate, and therefore bad for tea. Wet towards end of year, about 60 inches of snow fell.	Mild and dry spring, wet in May, retarding growth of cereals. Wet August, good for grass crop. Dry autumn and to end of year.	Very dry up to the middle of May, causing thousands of tea-plants to dry up and die. Rainy season very wet, especially in August. Dry autumn and so to end of year.

The above averages give 90 1/5 rainy days, 7 3/5 haily days, and 6 1/5 snowy days as the annual fall of moisture. The longest period of nearly continuous drought was from September 23rd, 1878, to 30th May 1879, for although moisture fell on 37 different days, yet the quantity, each time, was so small that it was almost inappreciable; the snow was especially deficient in quantity, hence the ground derived but little benefit when it melted, as there was barely sufficient to penetrate into the ground deeper than a couple of inches.

The average temperature (taken at sunrise and sunset) for the year is as follows:—

	January, February, March.	April, May, June.	July, August, September.	October, November, December.	Year.
Monthly Temp.	43°-51°	62°-69°	65°-69°	47°-54°	54°-61°
Do. Max.	64°	80°	76°	68°	80°
Do. Min.	36°	48°	59°	35°	35°

the thermometer (Fahrenheit) was hung in an open verandah W. aspect 6,400 feet above sea level. In the open air the thermometer would be about 8 degrees less during the night. Out in the sun in summer, it reaches to 138°.

The mean temperature at Assam is 77°, at Dehra Doon 70°, and Kangra 69°, the two latter places being found just cold enough to allow the tea plant to flush sufficiently, to enable a moderate income to be realized without any risk of climate. The mean temperature of Kotegurh is 57°, evidently much too low for the profitable cultivation of the tea plant.

The pretty little blue forget-me-not still continues in blossom, the yellow cistus has just come into flower in warm situations. The box tree is also in blossom. Mistletoe (vern. *ria*) is in berry, this parasite grows chiefly on the apricot and peach, it is also met with on the walnut, pear, poplar, olive, elm, and, rarely on the horse-chestnut, alder, oak, mulberry, and hawthorn; in some places it is given to cows in winter, to increase the supply of milk, so that it is useful for another purpose than mere flirting, under the point of view adopted by so many young ladies concerning it; I do not recollect seeing it in the plains, though I have seen it up at Narkanda and neighbourhood which is about 9,000 feet high. The holly tree (vern. *kaderu*) usually has berries (red) during this month, but this year I have not noticed any; I saw a few green berries on one tree, in November, but they never reached maturity; sheep and goats eat the leaves.

Green parrots migrate towards the plains during the early part of the month. The white-necked laughing thrush is now met with. Painted partridges fit for the table, and are very good eating.

Rats still continue very numerous, the frost not having yet been sufficiently severe to kill them off, or at all events get rid of a large portion of them.

The villagers, during the beginning of the month, gave their last ploughings, principally in the fields just previously cleared of the Amaranth (vern. *batu*) and hill potato (vern. *pahari alu*). They are also, while the weather is fine, continuing to cut and stack hay for fodder for their cattle, and collect pine leaves for bedding. Ropes are now manufactured from the little plots of hemp grown near the houses and brought round for sale: they are about ½ of inch in diameter, 30 feet long, and composed of 3 strands, and cost one anna each; they are merely hand-twisted. Manure is being carried out to the wheat and barley fields, for a top dressing; as stated last month, this is done as much as possible before the snow falls, so that when the latter melts, it may carry the manurial properties into the ground for the benefit of the crops; even if the manure has to lie for a month, at this time of the

year, it receives no harm, as the weather is so cold that no exhalation (or if any, only to a slight extent) occurs.

Food grains continue dear, wheat 8 seers (1 seer=2lb. av.) per Re. in bazaar, 10 seers in the villages, unground; barley 10 and 12 seers, scarce; Indian corn about the same.

An experiment has been made with growing Chinese sugarcane, the result tolerably satisfactory, shews that the production of saccharine matter depends on elevation, that whereas it yields none in the plains, it does so up here (6,400 feet above sea level), and judging from this experiment, I should consider an elevation of about 4,500 feet to be highly suitable for a paying yield of good saccharine juice. It ripens between the middle of October and end of November.

In the garden we have still snap-dragons, petunias, lobelias, pinks, nasturtiums, wallflowers, double and single chamomiles, candy creeper, mignonette, coreopsis, candy tuft, daisies, and sweet alyssum in flower. Some of the geraniums put into grass casings last month have flowered quite unexpectedly. Hyacinths, in pots on verandah, are sprouting; carnations flowering. Exotics, in pots, are now being put under cover to save them from the frost at night.

The chief operations in the garden are pruning, cleaning paths, opening drains, manuring.

Kotegurh, Dec. 31st, 1879.

The Indian Agriculturist.

CALCUTTA, FEBRUARY 2nd, 1880.

WELL IRRIGATION.

IRRIGATION as a means of improving our crops has lately occupied the attention of those Government officials more immediately concerned with agriculture, and for the time, the subject of irrigating from wells, has been discussed rather fully. It would be tedious to our readers were we to go over the entire literature that has appeared on the subject, including the interesting report of Mr. F. N. Wright, B.A., who was detached on the special duty of inquiring into the whole question, and the able Minute by Sir A. Clarke, with the practical suggestions of Mr. E. C. Buck and others. We will notice first the arguments for and against well irrigation, and next, the best mode of accomplishing their construction.

The first point to be ascertained is the value of water for irrigation purposes, and in spite of all that has been said against it, we must give our adhesion to the opinion that the use of water is of great service. We have been repeatedly told that the continued use of canal water has been steadily washing all the nutrition from the fields, but a little reflection will show that it is the abuse—not the use—of the water that has brought this about where it really exists. The mofussil resident does not require to be told that our system of using the canal water, is one subversive of all ideas of common sense. The rayat asks the chuprassie to turn on the water to his fields; this is done, and the water flows on and floods the entire area, to an extent undreamt of in the ordinary operations of Nature. At least twenty fold the quantity needed is used, and it is natural to expect that the excess on its way riverwards again, should carry away much that is valuable. It should not be forgotten that at each watering of a field, a depth of three feet is sometimes used; and that this is very much in excess of the ordinary rainfall. One watering by Nature does not usually exceed one-third of an inch. This waste of water is brought about by the system of charging so much per acre, instead of so much per inch in depth or per 1,000 gallons. There are of course difficulties in the way of a more exact mode of charging for water, and we may yet come to see the use of slightly increasing the land revenue where water was available, and thus having no separate charge at all, making all pay, who can have the use of it, and this whether they use it or not. Then it should be distributed in a sensible manner, and so as to make it impossible that it should be wasted, or that the land should be destroyed by it. It is now used at too long intervals; whereas it ought to be used more frequently and sparingly. In this the well will have a great advantage over the canal, inasmuch if the rayat prefers an excess of water, he will have to bear the expense of lifting it, and this he will not be so foolish as to do, the more so that he knows perfectly well, that a smaller quantity frequently supplied, is much more beneficial than thorough floodings at longer intervals. Two great objections are urged against irrigation from wells, and these are the absence of silt in well water, and the excessive cost of the system. These objections ought not to be permitted for a moment to interfere with the proposed action in the matter. Doubtless the water from our rivers, contains in solution much that, is valuable, hence the superior nature of alluvial soils, at the same time it must not be overlooked that the great object of using water at all, is to help in reducing the food constituents already in the soil, or placed there in the form of manure, to a form in which they become available for plant food, and this well water will do much more satisfactorily than canal water, and for many reasons. It will not, as a rule, be used in excess, but as it may be required, and this we consider one point gained, again, the agitation of the water consequent on its being drawn from a considerable depth, will ensure its æration, another point of importance, but the greatest benefit to be credited to well, as against canal irrigation we take it to be the more frequent waterings the land will get, and the small quantity of water that will be used at a time. And as to cost, the estimated cost of each well is put at Rs. 600, and the supply of water sufficient for 50 acres. This means a capital of Rs. 12 for each acre, which represents at 5 per cent. an annual charge of say 9⅗ annas. To this will have be added the cost of raising the water, all this would ultimately have to be borne by the cultivator, still we do not think it would amount to so much as he now pays for canal water. The experiments instituted by Mr. Wright, were made in the neighbourhood of Cawnpore, and we will take the canal charge of the North-Western Provinces for purposes of comparison. The total area of land irrigated in those provinces in 1878-79 was 1,735,978 acres, and the gross revenues from the canals was at the rate of Rs. 2-11-4 per acre irrigated, and we do not imagine that well irrigation would cost any more, another point that must not be lost sight of is that these wells being *pucca* would be easily kept clean, and pure water would always be available for drinking and cooking purposes. At present where rivers are not at hand, the water from filthy pools and *kutcha* wells is used to the detriment of health.

How are these wells to be constructed. Three ways are proposed. Government is advised to advance money to the cultivators or to the zemindars, or to construct the wells on State account. The latter seems the most advisable mode of carrying out this great work. Let the State construct wells wherever needed, and increase the revenue charge to such a rate as may be deemed sufficient to meet the extra cost of these wells. An addition of 12 annas per acre to the jumma will suffice, and the separate canal charge will be got rid of entirely. We do not anticipate that the rayat will raise any objection to this charge, as he will be provided with a plentiful supply of water for all purposes, whenever he may desire to use it, and not as is too frequently the case with canal water, when he chooses to bribe the departmental understrappers, and he

will be freed from one visit of the tax-collector. Separate charges for each item for which he is taxed are made on separate occasions, and each is made the occasion for further extortion by the putwaree or his chuprassie, or by both most probably. The charge added to the Government demand, added to his own subsequent expenses in raising the water will not amount to so much as he now pays for his intermittent supply. This latter portion—his own expenses—he does not reckon very highly, as he has his bullocks at any rate, and by a little judicious management can so arrange his work that the water raising will not interfere much with the ordinary work of his cattle. One point in levying this charge is worthy of attention, and it is this. The charge should not be made on the area irrigated by the well water, but on the area irrigable by it. The wells are not to be made for the rayat's convenience, but for his use, and it must be made his interest to use the water freely, with canal water the case is different. If one villager does not desire to use it, there is presumably more left for others, and thus the Government Canal Revenue may not be so very fluctuating after all, but with well water it is different, if a rayat declines to use the water in the well on his land, in many cases no other will be able to do so.

We trust soon to learn that some extensive and important district has been provided with these wells,' that the experiment may have a fair trial, and if successful, the speculation ought to pay, or the money can be had for four per cent., while the returns will be about five, thus allowing ample margin for collecting expenses.

FOODS, AND FEEDING STUFFS.*

THE blood has been compared to a river, bearing on its tide the imports from other countries and setting them down at intervals along its bank, and at the same time exporting from the whole area which it drains, materials given in exchange for those received. More correctly speaking, however, the blood flows over, and comes into the most intimate contact with every particle of the living body; and it not only takes up and ultimately carries out of the system the waste produced in the varied processes and operations of life, but at the same time it lays down wherever it flows, new material to build up and maintain the body in health and vigour. To repair this constant waste, and to supply the blood with materials to enable it properly to discharge its functions, food of a suitable kind and quality must be supplied.

Foods have been classed in various ways as 1st, flesh-formers, albumin, caséin, fibrine, gelatine, or proteids which always contain nitrogen; 2nd, fat-formers, fats, oils, &c., which do not contain nitrogen, but consist only of carbon, hydrogen, and oxygen, and 3rd, heat-producers, starch, gum, sugar, or amyloids, these like the fat-formers are destitute of nitrogen.

The distinctions between fat-formers and heat-producers is probably one which has no existence except in books; the truth seems to be that all foods are heat-producers; and that while those substances classed as fat-formers produce fat more rapidly than others, both proteids and amyloids assist in the process, and are in reality fat-formers, though in a lesser degree than fats and oils. Proteids are essentially necessary not only to produce muscle, but to repair the waste of nitrogen thrown off from the body in ammonia (H_3N). This class of food contains nitrogen, which is absent in the others.

Foods have also been classed under the following six heads:—

1st.—Water.

2nd.—Heat-giving, such as starch and sugar.

3rd.—Oil or fatty matter.

4th.—Flesh-forming material, gluten of wheat, legumen of peas, &c.

5th.—Ash or mineral matter, such as phosphates and carbonates, &c.

6th.—Woody fibre though chiefly indigestible, gives bulk to food.

1st. The importance of water as an item of food has in these latter days come to be regarded with much greater attention than formerly. The diseases that may be induced, and the mischief that is wrought by impure unwholesome water, contaminated by unspeakable abominations, is being more generally recognised and partly guarded against. That much yet remains to be done, even amongst highly civilised and wealthy communities is well known, and we rather fear that cattle and live stock of all kinds have yet to a very large extent to benefit by an adequate supply of wholesome water. The horse and cattle ponds of rural Britain and Europe generally, and the multifarious abominations of tank and nullah water in India are well known. Water is one of the most important articles of food for stock of all kinds; hence the advantage of turnips and other root crops for live stock. "Root crops" contain a very high percentage of water—in round numbers about 80 per cent. which has passed through the laboratory of Nature; and is of the wholesomest, sweetest, and most suitable kind. In turnips and other roots, cattle, in addition to this large percentage of water, receive about 20 per cent. of proteids and amylaceous substances. Drinking troughs for stock arranged to avoid the possibility of defilement from the excrements of the animals, and the mud carried into their drinking water by their feet and legs and stirred up by the animals entering the water, are highly desirable.

2nd. Heat-giving materials are present in all foods in greater or less abundance. The colder the climate or the season, the more of this class of food-stuffs will stock of all kinds require. If stock are exposed to the rigors of winter, or badly housed, they will require more heat-forming food, and be more subject to disease, so that in the long run it will be found a wise economy, properly to house and shelter farm animals; so that during great heat, or the chill of winter, a suitable temperature and protection may be attained, while at the same time the ventilation and sanitation of their surroundings are duly attended to.

3rd. Foods containing starch and sugar not only produce heat, by their combustions in the body, but they also produce fat. Oils and fats on the other hand are specially suited to produce fat, while at the same time by their oxidation in the blood they evolve heat. An animal, however, can as a rule take on fat more readily from substances rich in fats and oils than from compounds not fatty in their nature. For fattening purposes it has been estimated that a pound of fatty matter is equal to two and-a-half pounds of starch or sugar. Linseed (flax-seed) contains about ⅓ of its weight of oil; and when properly prepared and used, is one of the most rapid fat-producers known. The seeds boiled to a jelly, and mingled with chopped hay or straw, a little crushed oats, a little salt and cold water, make a bulky, highly nutritious and palatable feed. This method of preparing and using linseed has been recommended by a Veterinary Surgeon of very wide experience in England, who had ample means of verifying the results attained by this use of linseed. Oil cake or linseed cake is manufactured by extracting the oil by pressure in rolling mills. The residue or cake obtained contains about 12 per cent. of oil, and sells as high as £13-5 per ton, in the English market. Oil cake formed from linseed and free from adulteration, is perhaps one of the best substances that could be used for fattening. When used in excess or injudiciously, like all other foods, natural or artificial, it produces derangement of the digestive organs.

Rape seed is pressed in a similar way to linseed, and colza oil extracted. The residue, rape cake contains 11 per cent. of oil. Rape cake is cheap, compared with linseed, it does not however seem to "agree" with cattle or sheep so well as oil cake; and besides it has sometimes been adulterated with wild mustard (*Sinapsis Niger*) which produces inflammation of the bowels, and in some cases death. Many valuable animals have been lost by the injudicious use of this and other cakes. It is an easy matter to determine if the cake be adulterated. Make a small quantity into a paste with water; the characteristic smell of mustard will reveal itself if present. All danger from this source may easily be avoided by procuring the cake from some respectable dealer, who will guarantee its purity, and whose interest it is, that his wares should be comparatively, if not absolutely pure and wholesome.

In this connection it may not be inappropriate to quote the results arrived at by the late Professor Anderson, Professor of Chemistry in the University of Glasgow, and chemist to the Highland and Agricultural Society of Scotland. The following is an extract from a lecture delivered by the Professor at a meeting of the Society of which he was chemist. "During the past year (1867) I have found " bran, grass seeds, carob beans, French nut cake, and " a variety of other seeds, in oil cake of British manufacture, " Many of these are undoubtedly due to the inferiority of " the linseed used. For cargoes are often met with, con- " taining not more than 60 or 70 per cent. of actual linseed, " the remainder being the seeds of weeds, and in such cases " the manufacturer is able to shelter himself behind the " statement that he added nothing to the linseed; but in " other cases there can be no question about the deliberate " addition of the extraneous substances, This is always " the case with bran, carob beans, nut cake, and the like; " and in one case I was able to trace the fact, that French " nut cake had been brought from Hull to an oil mill in " one of the large towns of Scotland, where it was ground " down and mixed with oil cake."

Cotton cake is obtained from the seeds of the cotton plant. Made from the whole seed it contains 6 per cent. of oil, probably more. When first introduced as an artificial feeding stuff, the husk of the seed was unbroken because the seed had not been ground. This caused considerable loss, for the indigestible husks frequently lodged in the bowels, and caused inflammation and death. Deprived of its husk, it is now known as decorticated cotton cake. It contains about 10 per cent. of oil, and answers very well when cattle are first put up to fatten; but as they increase in weight, practical results seem to point to the fact, that no cake pays better than oil or linseed cake. During the year 1874, the best brands of decorticated cotton cake brought as high a price as £10-5 per ton.

Palm nut meal when the animals well eat it, is unrivalled for producing a large increase of milk or butter. To the bulk of animals, however, it is not usually palatable, but it may form one of the articles in a judicious mixture which the agriculturist who has an intelligent understanding of the merits and properties of food-stuffs may safely be left to make for the use of his own animals. It is much cheaper than linseed cake being only about £8-10 per ton.

Cocoanut meal is, like palm nut meal, valuable for its milk and butter-producing powers.

4th. Flesh forming materials must form a part of all feeding stuffs, whether natural or artificial, if the animal is to be kept in health and condition.

The proportion of proteids necessary in food-stuffs will vary with the waste of tissue. Hard-wrought animals require a large proportion of flesh-formers to make good the tear and wear of muscle nerve and viscera. The judicious use of maize as feeding for hard-wrought horses, and the good result obtained in fattening from the careful employment of Indian meal, ought probably to be better known. Disease, irritation, or a restless disposition, as well as irregularity in feeding, increase very much the waste of protieds in the system. A sheep in "rot" (liver disease) produces less mutton, and of an inferior quality, than out in health. A restless cow thrives worse than one of a gentle disposition. Regularly fed cattle always thrive best, and at least cost, provided they get sufficient exercise, are kept comfortable and sufficiently warm to prevent either undue perspiration or the dangers that may follow chills. The quieter that cattle "put up to fatten" are kept, the greater weight of beef they are likely to lay on from a given quantity of food-stuffs. These short general statements common place and trivial as they may seem, are, it seems to us the foundation principles, some of them at least of the management of stock.

5. The importance of the mineral constituents of foods cannot, we think, be too much insisted on. There must be phosphates and carbonates to form bone, or the legs of pigs, sheep, and cattle will give way, and the general health of the animal will suffer. The use of common salt is far too little known, or if known, then not practiced. Breeders of stock of all sorts would do well to provide their farm animals with salt, pigs and horses can have it in their *mash*; and cattle can have rock-salt to lick. The addition of salt to food, is as beneficial, and can be relished as well by farm stock as their owners; and tends to prevent disease, as well as supplies a most important food constituent. All foods, whether natural or artificial, should have salt added to them. The other mineral constituents necessary to build up a healthy frame, are present usually in sufficient abundance in the various food-stuffs supplied to stock, whether natural or artificial.

The question as to the methods of feeding and the proportions of feeding stuffs best suitable for farm animals, is one of the highest importance, and forms a series of the most difficult problems within the whole range of farm economy. Minute and elaborate experiments have been carried on by chemists, physiologists, and others, who in addition to their scientific knowledge have exhibited a masterly grasp of the practical details of farm management. The details of these experiments are very well worth the careful study of the professional agriculturist; but it cannot, we think, be too frequently insisted on, that even the very best experiments conceived and conducted with the greatest care will frequently result in disappointment; because the sum of the conditions necessary to produce desirable results, are sometimes beyond the power of the experimenter to bring together.

The intricacies of the problem of the breeding and rearing of farm animals—so that at the least possible expense, and in the shortest period of time, the greatest and most nutritious weight of pork, beef, mutton, fowls, milk, butter, &c., can be placed in the market and command a ready sale—are of a kind that demand ceaseless vigilance and the constant supervision of trained observers. The *breed, age,* and *constitution* of the animals are each of them, matters which the agriculturist should study and provide for; and due provision has to be made for the evils that follow from the extremes of *climate* or *season*; and any advantages these may offer, seized on and made available for the general purpose in view. The course of feeding or treatment suitable for one breed may not prove so successful with another. The various breeds of farm animals differ as much perhaps as it is possible for animals to differ, and yet retain the same general characteristics.

The causes of the production of these breeds and varieties may generally be classed under two heads: 1*st*, Natural Selection. 2*nd*, the interference of man conscious or unconscious; and one of the leading results to be sought after unceasingly by breeders and rearers of farm stock of all kinds, is to produce a race or breed of animals which, while inheriting the general qualities of the species or genera to which they belong, shall possess in a marked degree, and unite in *one* breed or class of animal the special qualities inherited by sire and dam. How successfully this has been accomplished is visible in the improved breeds of all animals. Some of the dangers resulting from what we may venture to call *high breeding*, we pointed out in our remarks on the general treatment of farm animals.

EDITORIAL NOTES.

WE have lately been testing a new plough made by Mr. Wm. Martin, Phuppoond Indigo Concern, Etawah. When it was first brought to our notice, it struck us as being the very thing that was wanted, and a subsequent trial on the field confirmed this impression. We had it tried the other day, and compared it with the work done by sundry other ploughs of recent make, as also with the common village plough, and during the whole time there never existed a doubt as to the great superiority of the new plough. The villagers who tried it, were in perfect raptures about it, and the Bengalee is not as a rule, very demonstrative. They were loud in praise of it, as it entailed very little work on their cattle, and besides making a wide furrow, it turned the entire sod upside down. Mr. Martin has wisely steered clear of glaring innovation; he has simply taken the common country plough, and exercised a deal of common sense, and experience of Indian cattle, in effecting a very slight alteration in the share, which he continues upward with an eccentric curve, thus forming the mouldboard, which inverts the sod without any perceptible effort. The advantages it has, are many; we may enumerate a few.

1. It is not a new plough in the sense of an innovation, and is therefore not an eyesore to the rayat.
2. The construction is of the simplest, and it can be made or repaired by any village carpenter and smith.
3. It costs little, Mr. Martin, we are told will be able to sell them at about Rs. 4 each.
4. The draught is exceedingly light.
5. The plough itself is light, weighing only 13¾ seers.
6. The ploughman can twist the bullocks' tails, an important item in his (the ploughman's) estimation.
7. It does its work so thoroughly that one ploughing will do as against four of the country plough.

There are other advantages possessed by this plough, but let these suffice. We understand Mr. Martin is taking out a patent for the invention, and if the obtaining of a patent is contingent on the article actually possessing advantages, he should have no difficulty in securing it.

THE Punjab Agri-Horticultural Society has closed a busy season, that of 1878-79 having resulted in a large distribution of fruit trees, which, if continued, cannot fail to have a beneficial effect on the future of the province. It does seem strange that, with such a climate as prevails in the Upper Provinces generally, fruit and good vegetables should be so scarce, but such is the case. Visitors to Calcutta from those provinces, express their astonishment at our supplies of vegetables, whereas with one of the finest climates in the world, they themselves should grow everything necessary for table use to perfection. As an instance, showing what can be done, we have known a gentleman cultivating peas all the year round, although the *malees* persisted in deprecating their growth except at the usual season. All the extra treatment they required was, that during the rains, they had to be protected by a slight covering of mats to prevent their being beaten down. At present there are no fewer than 1,436 trees bearing fruit in the Society's gardens. And during the season the distribution amounted to 3,708 fruit trees and an immense number of plants, shrubs, and flowers. A good deal of attention was devoted to the raising of vegetables, the object being principally to provide a supply of acclimatised seed, and in this the officials report success. Of peas alone nine maunds were raised, and have been kept as seed for the following year. The Garden school is an interesting feature in the Society's work. There are 15 boys attending it, and they are taught practical gardening and a smattering of English, sufficient to enable them to read the names and numbers of the plants.

The experiments with cusco maize do not seem to have been successful, and this may be said generally of the trials made in different parts of the country; neither did success follow the trial of Bamieh cotton. This is much to be regretted, as this variety is a great improvement on the indigenous class of cotton, and had it been found to suit our climate, it would have proved an additional source of wealth to our agricultural classes. Besides, our cotton industry is languishing, and we require a new infusion of seed by way of improving the *jat* of our indigenous plant.

A GOOD deal of attention has lately been bestowed on the advisability of giving prominence to the value of the ground-nut as one of our agricultural products. This nut is valued as an article of food in many parts of the world, notably in Spain, and in the United States, but is only cultivated here to a very limited extent. And this indifference is all the more astonishing when we reflect on the difficulty we frequently have here, in providing food for the people during the times of famine, &c. It has besides other good qualities; for instance, a good quality of oil, suitable for soap-making, is extracted from it, and the refuse is capital cattle-food. It does not cost much to cultivate, and the returns are liberal. In a district in the Berars 259 acres were sown, and the return was at the rate of 800lb. per acre. If an acre can produce 2,240lb. of food for human beings, the plant ought to win its way among us. The food is of a sort agreeable to the palate, and from the quantity of oil it contains, it should be nourishing. The quantity of oil already obtained has varied from 33 to 50 per cent., and the cake which remains has been found quite as nutritious as linseed cake for cattle-food. An analysis of the nut, with a view to its being valued as food, shows it to be "richer than lentils in flesh-forming constituents, while it contains more fat and more phosphoric acid than lentils or peas." The present cultivation in India amounts to:—

Madras ...	... 34,632 acres,
Bombay ...	... 70,350 ,,
Bengal ...	... To a very limited extent,
North-West Provinces	... Very little grown,
Punjab ...	... Almost none,

and in proportion in the other districts of India. The consumption of this article in France alone is 111,443,366 kilogrammes, equal to about 110,000 tons, 92½ per cent. of which she imports from the western coast of Africa, and there is nothing to prevent India taking a leading part in this trade.

SUNDRY experiments have lately been tried in Queensland Australia, in the cultivation of rice, and so far they have been very successful. In October, corresponding with our April, a crop was sown, and reaped in the following January. Immediately thereafter the fresh seed was sown, and a second crop reaped in April. Thus the land produced two crops between October and April, or in six months, the quantity of grain aggregating 68 bushels per acre. As the bushel contained 50lb., this represented a total production of 3,400lb. per acre. How, then, does India look with her average of 1,200 to 1,500lb.? It seems that with the finest climate for agricultural purposes, we are allowing every other country to go ahead of us. Our cotton cultivation has fallen to a very low ebb indeed, so far as outturn is concerned, this latter being about one-fourth of that of America, and now we are likely to be beaten by Australia in a grain which is peculiarly an Indian produce. Extensive tracts of land exist in Queensland suitable in all respects for this cereal, and from the known energy of the colonists we may conclude that a large trade will speedily spring up. It seems only a few years since we heard that the cultivation of the vine was being tried on a commercial scale, and now we

occasionally read of the near prospect of Australian wines competing with those of France, Spain, and Germany. In this country an extensive system of irrigation is necessary for the successful growing of rice. In Queensland this is not required; the soil is good and thoroughly suitable, and the moisture is obtained from occasional showers and heavy dews, and hence the cost of cultivation is materially decreased. Labour is more expensive, but the amount of work that can be done with machinery is great, and if labour be found to be expensive, the use of machinery will be resorted to, in order to overcome this difficulty; and while we are plodding along with our primitive ploughs and our cultivation of about three inches, these colonists will be turning up fresh soil to the extent of 10 to 15 inches, and producing two to three times as much per acre as us, at an infinitesimally increased cost, and thus we will find another branch of commerce taken out of our hands.

THE Ceylon Planters' Association invited Professor Hughes to visit Ceylon, and make a careful examination of everything connected with their great industry coffee. He arrived in Ceylon in November 1877, and immediately made a tour through the island, collecting information and samples of soil, leaves, &c., and to enable him to complete his critical examination. His report is now published, and we have been favored with a copy. In it will be found all that a coffee planter need know of the scientific branch of his profession, the explanations and general remarks being particularly plain, and at the same time full. The section which treats of manure, and which covers the greater part of the book is exceedingly interesting, the most minute details of analysis being given. A chapter is devoted to the important subject of cattle-feeding, and a table given showing the value of manure produced from 32 different kinds of cattle food. It appears from this table that decorticated cotton seed cake stands highest, a ton of it producing manure worth £6-10, while a ton of carrots—which are at the bottom of the list produces manure to the value of four shillings only. The book, as we have said, is of peculiar value to coffee planters, but will also prove useful to all engaged in agriculture, and copies are we observe, to be obtained from the Secretary, Ceylon Coffee Planters' Association, Kandy.

THE Report of the operations at the Bhadgaon Farm, Kandeish, for the year 1878-79 is to hand, and deals fully, very fully, with what has been done during the year. Some experiments were made with Hingghat cotton, which resulted in an average production of 69lb. per acre, which the Superintendent considers good. We can scarcely understand this, as a couple of paragraphs further on he describes a small plot which produced at the rate of 230lb. per acre. Surely 69lb. make a small outturn. In America, the average is close on 300lb., and although we do not look for such a large outturn here, where agricultural science is very backward, still we think that 69lb. per acre should not be called "good." The experiments made with Bamieh cotton were all failures, and this the Superintendent attributes to the soil of Khandeish being "too stiff," and "the heat and rainfall too severe." A series of experiments with jowari, has resulted in an outturn of 399lb., per acre on the average of four years, which "is considered a good fair crop." If, after several years' work, these experimental farms can only show a good fair crop, we fail to see any reason for congratulation. We imagine their object to be to show the ryot how to improve his farming, and how to raise much larger crops, and if they do not succeed in raising better crops than those called "good fair," we are forced to admit that they have failed largely in the object for which they were instituted. The Superintendent mentions a curious fact, *viz.*, that the students object to such training as would take them out of doors. How youths are to become practical agriculturists without instruction in the field is beyond our comprehension. And if the natives of this country wish to become good agriculturists, they must make up their minds to learn the work thoroughly.

During the year the farm was worked at a loss of Rs. 950, and no charge for superintendence is made, and yet we pretend to be astonished at the indifference of the ryots, who will not be induced to follow in the footsteps of these experiments. They are very conservative we know, but when the farms point out to them a palpably better *and more profitable* mode of working, they will not be slow to take advantage of its benefits.

WE have been favored with a copy of the prospectus of the Maiji Exhibition and Horse Show, Khandeish, to be held in March ensuing, the opening day to be 1st March. The classification is particularly minute, and the prize money high. This should give all who care to compete a chance. For mares as high a sum as Rs. 100 is offered as a prize. Under the heading of agricultural products, every conceivable sort of grain, fruit, vegetable, and root is represented, and under "miscellaneous," a variety of articles are ticketed with prizes, as articles of clothing of local make, carpets, blankets, &c., nor are farm implements neglected, for we observe in the list carts of various sorts, and native field implements. We would direct the Collector's attention to the value of the maxim *Bis dat qui cito dat*, in connection with the rewards, as we are credibly informed that several prizes and certificates of honor obtained at the Katiawar Exhibition of 1877 have not yet been distributed to the anxious would-be recipients.

THE Administration Report of the cotton department for 1878-79 is to hand, and while it contains much that is interesting, it does not offer food for satisfaction, or for much hope regarding the future. The small and irregular outturn is a cause of astonishment. In one district we find it 30½lb., and another 336lb. The average in the Bombay Presidency, including Native States is 37½lb., and how rayats continue to grow this fibre year after year, is a marvel to us. Cotton sells wholesale in Bombay at Rs. 224 per candy, which is 4 7/12 annas per lb., and we do not suppose the rayat gets more for his crop then 3½ annas; this means a gross income of Rs. 8 per acre. That this estimate is as nearly correct as may be, is proved by the return of average prices ruling in the different districts, which is 3 annas 8 pies per lb.

Notwithstanding the fact that isolated prosecutions were instituted under the Cotton Frauds' Act, it would appear that Indian cotton compares well with American in cleanness. In four bales American an average of 15 per cent. was lost in the manufacturing process from cotton to yarn, while in four of Indian the average was 14 per cent.

MR. HUME, in his *Hints on Agricultural Reform*, relates an incident in the private life of late Lord Mayo, which indicates the true insight which the lamented Viceroy had into the condition of this country, when he resolved to set up a new Department of State to look after the interests of agriculture. Lord Mayo, he says, was probably the only Governor-General who had farmed for a livelihood, and made a living out of it. When he came of age, his father could not afford to make Lord Mayo any allowance, but he turned over to his son one of his farms to make what he could out of it. This Lord Mayo managed himself, and made enough out of it to enable him to attend Parliament regularly from after Easter to the end of the Sessions. The lessons of thrift and economy thus learnt by Lord Mayo in the management of a farm on a small scale, he turned to account in the government of an empire. He found India to be a vast estate of which the State was the landlord, and instinctively perceived that the salvation of the country chiefly lay in its agricultural improvement. He accordingly organised the department, and would have worked out its results in the way he had contemplated, had his life not been cut off in the midst of a most useful and honourable career.

OUR correspondent in Johore writes as *Straits Times* as follows under a recent date:—"The traveller bound for any one of the now famous mountain ranges here is struck at the number of the pepper gardens and Gambier plantations he meets with, not only on account of their number but on account of the sightliness of some of them, more especially the pepper gardens, round about which hardly a single weed is, to be met, and the plants being almost all in the most perfect trim and planted at regular distances of about six feet from each other. The Gambier plantations are also worthy of some attention, one sees the Chinese busily engaged in boiling the leaves and preparing the syrup into squares for the Singapore market; and to their credit be it said that of the many thousands who support themselves by this cultivation, the majority are orderly and strikingly industrious labourers. It is to be hoped that now Europeans are settling in the country, that the Tow-kays will

impress upon their men to deal fairly with the new settlers, from whom they will, in all probability, benefit in the shape of profitable employment."

THE *Monitor Sul-Mineiro* warmly advocates the general cultivation of the so-called Batata de Demarara (Jerusalem artichoke) because of its great ease of cultivation, its large yield and its wholesomeness. It does not require virgin soil, it suffices to plant pieces of the vine or stalk, it requires no after cultivation, as it takes possession of the ground completely, it yields three crops of tubers a year, and it needs no replanting, as sufficient small tubers and pieces of vine remain to renew the crop. In starch it is at least as rich as mandioca and is excellent food, above all when cooked, for domestic animals. Besides which, if suitably fenced, hogs can be allowed to dig for themselves and thus learn practically the g old maxim : "Root little hog or die."—*Rio News.*

A WORLD'S fair is to be held at Krishnagurh in February next from the 12th to the 17th, in combination with an agricultural exhibition and cattle show. Besides the usual inducements held out to exhibitors of agricultural produce and machinery, animals and poultry, prizes will be offered for proficiency in athl etics.

A WELL-KNOWN arboriculturist, M. Alphonse Lavallée, Treasurer of the Société Centrale d'Horticulture de France, publishes in *L'Agriculture* the results of an attempt made by him to banish the terrible phylloxera out of the vineyards. In his immense plantation and tree-nursery at Segre, M. Lavallée has cultivated for some years a number of Asiatic vines, and these have been always steadily and, as he thinks, purposely avoided by the insect. Although the latter has been conveyed to other vines in their neighbourhood, it has refused to forsake the occidental vine for the oriental. M. Lavallée has sent specimens of these Asiatic vines to various persons and societies occupied with the campaign against the phylloxera ; but in almost all cases they have refused to have anything to do with them on account of the unprepossessing appearence of the twining oriental grape-vine, which some described as too exuberant and honeysuckle-like. On the other hand, Madame Ponset, the owner of the great vineyards of the Lande de Pomerol, accepted his presents and counsels ; she methodically followed out the latter. She planted three species of Asiatic vines—the *ampelopsis acanitifolia* of Northern China, and the *vitis peterophylla* and *vitis inconstans* of Japan—in the immediate neighbourhood of plants peopled with the insect. Whilst the devastations of the phylloxera went on all round, three Asiatic immigrants throve prosperously and were externally unaffected. Madame Ponset, according to her adviser's counsel, next had the roots probed by three experts, all of whom reported that the vines were perfectly sound and free from the suspicious knotty swelling which is a symptom of the presence and operations of the phylloxera. M. Lavellée now proposes to graft the various French vines upon Chinese and Japanese roots.

A DIFFICULT ag ricultural problem is thus treated by the *Bombay Guardian* : A friend from the South of India was speaking to us the other day of the great benefit that had accrued to the fields in the famine districts from the respite which they had had from cultivation in the last two years. Such harvests as have appeared this last season have not been witnessed for a great many years. This brought to our mind the institution of a Sabbatic year given to the Jews by God, but of which they do not appear to have had faith to avail themselves. There can be little doubt that it would have been for the good of the fields, and consequently for the good of the people, if they had observed this command and allowed the lands to lie untilled one year in seven, providing for the necessities of that year in the six years of abundance. The Jews, as we said, did not observe this law, and after the lapse of about 420 years from the time of David, the Lord claimed the 70 years due him and carried the Jews into captivity for that period. Immediately after the six days' creation, God sanctified the seventh day, and the Sabbatic rest belongs to creation, though through man's apostasy it is at present deprived of it.

OUR readers will find the Index for last year's volume with this number.

HIMALAYAN LEPIDOPTERA.

II.

(Continued from page 11.)

LEMONIIDÆ.

Libythea, *Fabr.*

L. MYRRHA, *Godt.* This insect is most frequently met with near water, though I have taken it in many other places. It frequently settles on rocks and stones, often at the end of a dead twig, where it so exactly resembles a dead leaf that it is almost sure to escape observation. Expanse from 2in. to 2·1in.

L. LEPITA, *Moore.* Far commoner than the preceding. It is on the wing also from March to November, and has exactly the same habits. Expanse from 1·8in. to 2·2in.

Dodona, *Hew.*

D. DURGA, *Koll.* Met with everywhere throughout the year. I have taken perfect specimens as late as the middle of November. Expanse from 1·2in. to 1·7in.

LYCÆNIDÆ.

Lycæna, *Fabr.*

L. PHLÆAS, *Linn.* This insect is more commonly known under its generic name Chrysophanus Phlæas. It is a common insect throughout the N. W. Himalayas, occurring plentifully on grassy hill sides, in gardens, and in fact it is ubiquitous. Expanse from 1·2in. to 1·4in.

L. PAVANA, *Westw.* Not quite such a common insect as the preceding, but occurs in similar places, and also from early spring to late autumn. Expanse from 1·1in. to 1·3in.

Cupido, *Schrank.*

C. BÆTICUS, *Linn.* A very generally distributed insect, occurring commonly in the plains in the winter and in the hills throughout the year. It has a very rapid, jerking flight, but settles continually on flowers, &c. Expanse from 1·1in. to 1·3in.

C. DIPORA, *Moore.* This pretty little "blue" is common wherever there is grass, on hill sides, meadows, &c. It is on the wing from March to November. Expanse ·8in. to 1in.

C. NAZIRA, *Moore.* I have met with this insect most frequently near water, though it occurs occasionally in other localities. I have taken good specimens at Simla as late as November 15th. Expanse from 1in. to 1·3in.

C. KASMIRA, *Moore.* This is the commonest of all the "blues" in the hills, it actually swarms wherever the berbury, its food-plant, grows. There seems to be a constant succession of broods, perfect specimens are to be taken at all seasons. Passing through the lovely Kulu Valley in July this year, it was the commonest butterfly on the wing, literally thousands were observed sucking up moisture in damp spots. Expanse from 1·3in. to 1·5in.

C. CHANDALA, *Moore.* This insect is a regular "groundling," never flying above the earth more than a few inches, and always settling on the grass or equally low-growing plants. Common in the hills throughout the year. Expanse from ·9in. to 1·1in.

Zephyrus, *Dalm.*

Z. SYLA, *Koll.* I have only taken this insect amongst oak trees, on the leaves of which it settles, and on which most probably its larvæ feeds. Common during the summer wherever oaks grow, and worn specimens are to be met with late on in the year. Expanse from 1·2in. to 1·4in.

Ilerda, *Doubl.*

I. TAMU, *Koll.* This insect was very common last October, but the specimens were all worn. I have taken specimens in Simla early in April, again about midsummer, and there is also an autumn brood. I have always taken it near water amongst rank vegetation. Expanse from 1·2in. to 1·7in.

I. SENA, *Koll.* An ubiquitous insect, occurring everywhere at all seasons. Expanse from 1·3in. to 1·4in.

Deudorix, *Hew.*

D. EPIJARBAS, *Moore.* Very plentiful throughout the autumn near water in the hills, and on the Poinsettia flowers in Calcutta during the winter. Expanse from 1·2in. to 1·8in.

D. VARUNA, *Horsf.* Also occurs both in the plains and hills. In Calcutta it is the commonest species of the genus during the winter, and is fairly plentiful in the hills during the autumn. Expanse from 1·3in. to 1·5in.

D. Nissa, *Koll.* This insect chiefly frequents oaks, but also occurs amongst bushes and rank herbage on the borders of streams It is on the wing from June to October. Expanse 1·3in. to 1·5in.

Amblypodia, *Horsf.*

A. Rama, *Koll.* More frequently met with amongst oaks than elsewhere, though this November I have observed many males "imbibing" by the sides of streams at Simla. There are several broods, appearing all months from March to November. Expanse from 1·2in. to 1·5in.

PAPILIONIDÆ.

Eurema, *Hübn.*

E. Brigitta, *Cram.* This insect is more usually known by its name Terias Drona. Very common in the hills throughout the autumn, thousands of males may be observed sipping up moisture on the banks of hill streams from August to November. They gather in little groups for this purpose, flying off when disturbed only to return to the same spot hereafter. Expanse from 1·5in. to 1·7in.

E. Hecabe, *Linn.* Also a common autumnal hill insect, but it is also to be met with in the plains in the winter. Expanse from 1·4in. to 1·8in.

Pieris, *Schrank.*

P. Brassicæ, *Linn.* Generally known in India as P. Nepalensis. This insect is double brooded, the first appearing in March and April, the latter in late summer and autumn. Most commonly met with in gardens and fields. Very common in Cashmere, and I took specimens far up in Ladakh this summer. Expanse from 2·5in. to 2·7in.

P. Canidia, *Sparrm.* P. Gliciria, the common name of this insect in India, appears to be merely a synonym of Canidia. This butterfly is not apparently restricted to two broods like Brassicæ, specimens are to be taken everywhere throughout the year. Also very common in Cashmere and as far east in Ladakh as Leh. Expanse from 1·7in. to 2·3in.

P. Mesentina, *Cram.* Distinctly double brooded in the hills, the first appearing in April, the second in October. I have taken a few specimens in Calcutta in March. It has a very swift flight, and but for its settling occasionally would be a very difficult insect to capture. Expanse from 1·8in. to 2·2in.

Delias, *Hübn.*

D. Belladonna, *Fabr.* This insect is very uncertain in its appearance, some years it is fairly common in the hills, others not a specimen is to be seen. I took three specimens at Kotgarh last year, and several in Simla, but I have not seen a single specimen this season. It is either double brooded or it hybernates, I am not quite sure which, at any rate I have taken worn specimens in the spring of last year at Suni near Simla. It has a weak flight, and seems particularly fond of the flowers of the Dahlia. Expanse from 2·4in. to 3·3in.

Catopsilia, *Hübn.*

C. Pyranthe, *Linn.* The generic name is more known as Callidryas. All three species that occur in the hills make their appearance about the same time, *viz.*, during the rains, and a few specimens of each, hybernated, are met with the following spring. All are equally common in Calcutta during the winter. They have a very strong, swift flight, and but for their continually settling on flowers, &c., it would be very difficult to make up series of these insects. The expanse of Pyranthe is from 2·1in. to 2·4in.

C. Pomona, *Fabr.* More generally known as Hilaria. Expanse from 1·8in to 2·8in.

C. Crocale, *Cram.* Also commonly known as Alcmeone. Expanse from 2·1in to 3·2in.

Gonepteryx, *Leach.*

G. Rhamni, *Linn.* Kirby relegates the Indian variety of this insect named Nepalensis to the limbo of synonyms. It has just the same habits and appears at the same time as the home "Brimstone," and as far as I can see is identical. Expanse from 2in. to 2·7in.

Colias, *Fabr.*

C. Croceus, *Fourcr.* The well-known name "Edusa" must give way to Croceus, that name having been given to this insect in 1785, two years before Fabricius named it Edusa. I am of opinion that this insect is double brooded, the first appearing in the spring, the second late on in the summer. The former is the most numerous. It occurs throughout the Simla Hills, is very common in Cashmere about midsummer, and occurs throughout Ladakh in favorable spots. Expanse from 1·4in. to 1·6in.

C. Hyale, *Schmett.* Kirby gives this as a variety of Croceus. Of the two it is much the rarer, but occurs at the same time and in similar localities. Expanse from 1·5in. to 2·1in.

Ixias, *Hübn*

I. Pyrene, *Linn.* I took good specimens in October, 1878, and again in August this year. It is a most variable insect, my specimens from Darjeeling are nearly double the size of those taken by me at Kalka in October, 1877. My Simla, Kotgarh, and Calcutta specimens are all about the same size. The females differ very much, my Calcutta ones are yellow, my Kotgarh ones nearly black, and I have taken quite white ones in the Bheerbhoom District, Bengal. My plains specimens were all taken in gardens or near hedges bounding fields, my hill ones always near water. Expanse from 1·7in. to 3in.

Callosune, *Doubl.*

C. Etrida, *Boisd.* I took two or three specimens of this pretty little "Orange Tip" on the Hindustan and Thibet road above the station of Kotgarh in October last year, also a few specimens at Fagou and also in Simla the same season. This year I have only taken one specimen in Simla. It does not seem to be peculiar to any one class of locality, I have taken it on the summits of hills, and in valleys near water. Expanse from 1·3in. to 1·6in.

PAPILIONINÆ.

Parnassius, *Latr.*

P. Hardwickii, *Gray.* I have never taken it in Kotgarh itself, but as it occurs at Narkunda, the next stage, I have included it. I have only taken this insect in the Simla district on the tops of bare hills covered with grass and short herbage, but on the Rotang and Jalauri Passes, it occurs amongst trees and bushes where the grass and vegetation is above a foot in height, and wild flowers abound in profusion. It has a rather slow flight, but when disturbed, it moves very rapidly and with apparently little exertion, the wings remaining outspread the whole time. Expanse from 2·2in. to 2·4in.

Papilio, *Linn.*

P. Erithonius, *Cram.* A very generally distributed insect. In Calcutta during the cold months it is the commonest species of the genus. It is fairly plentiful in the hills in the late summer and autumn, occurring everywhere. It has a very strong, swift flight, but luckily for the collector settles frequently where there are flowers. In Calcutta it feeds on the bael tree (Ægle Marmelos), as this tree does not grow in the hills, I imagine this insect must feed on some allied orangeacious tree, probably Xanthoxylum arramaticum, Vernacular name "Taij Bul," which is the food plant of P. Protenor, Polyctor, and Polytes. Expanse from 2·5in. to 3·5in.

P. Polyctor, *Boisd.* The commonest of all the genus in the Simla Hills. In July and August I have seen literally hundreds of males sucking up moisture in damp spots on the margins of the Simla river. It is double brooded, the one that comes out in the spring is far less numerous than the summer one, the specimens also are far smaller. Worn specimens are to be met with as late as the middle of November. Expanse from 3·5in. to 4·5in.

P. Protenor, *Cram.* Not quite so common as the preceding, but is double brooded also, and makes its appearance at the same time. The male has a patch of white scales on the lower wing where it is over-lapped by the upper, which generally is hidden. I have noticed though that when courting the male and female fly round and round each other, the former opening wide the upper from the lower wings, causing the white patch to be very clearly seen. Expanse from 3·2in. to 4·9in.

P. Cloanthus, *Westw.* I have only taken one specimen at Kotgarh, it is a somewhat rare insect throughout the Simla Hills. It apparently hybernates, as I have taken worn specimens very early in the spring, but it is out most commonly in June, and good specimens are again met with in August. I have taken a good many on the top of Tarwa Davi, a hill opposite Simla, flying backwards and forwards over the tops of bushes and low oaks near the summit of the hill, also flying round and round the top of a tall white Poplar tree in a garden on the outskirts of Simla. I climbed to the top of this tree, and by getting my net out beyond the highest branches, I was able with a little patience to secure 3 or 4 specimens in a morning. It is also fond of sitting with closed wings on the margin of streams, sucking up the moisture. Expanse from 3·2in. to 3·5in.

P. MACHAON, *Linn.* Most frequently met with on grassy hill sides, though I have taken many specimens flying along the beds of streams. A small brood comes out in the spring, a much larger one in the summer. I have met with it throughout Cashmere, and a variety ? with short almost obsolete tails in Ladakh, where its food plant is the wild carrot, which abounds there. Expanse from 2·3in. to 3·3in.

P. POLYTES, *Linn.* Generally known as P. Pammon. It is a very generally distributed Papilio, occurring very plentifully in the plains, particularly in Calcutta during the cold months, and somewhat sparingly in the hills. I have taken it most frequently near Simla in the beds of streams, though occasionally it occurs in other localities. In Calcutta it feeds on Ægle Marmelos, in the hills on Xanthoxylum arramaticum. Expanse from 2·7in. to 3·8in.

HESPERIDÆ.

Casyapa, *Kirb.*

C. CHAYA, *Moore.* Common both in the hills and on the plains throughout the year. Occurs everywhere. Expanse from 1·1in. to 1·4in.

C. MANGALA, *Moore.* Fairly common in the neighbourhood of Simla near water. Occurs throughout the year. Expanse from 1·3 to 1·6.

Ismeno, *Swains.*

I. EXCLAMATIONIS, *Fabr.* I first took this insect in the Kulu Valley in July, 1879, and a little later on it was very common in Kotgarh, particularly on the flowers of the Zinia. I have never come across it at Simla. Expanse from 1·9in. to 2 3.

Pamphila, *Fabr.*

P. AUGIADES, *Feld.* It is common both in Calcutta and in the hills, occurring in the latter generally near water. A late summer and autumn insect. Expanse from 1·2in. to 1·4.

P. MÆSA, *Moore.* I have taken this insect at Kalka in October, 1877, at Ulwas near Pangi in May, 1879, in the Kulu Valley in July, and at Kotgarh in August. It seems very fond of Thistles, and I have taken most of mine at rest on those flo wers. Expanse from 1in. to 1·2in.

Plesioneura, *Feld.*

P. DAN, *Fabr.* A somewhat rare "Skipper" in the hills. It keeps to one small space generally in the gorge of a mountain stream, up and down which it flies, even returning to the same spot if disturbed. It occurs throughout the summer and autumn. Expanse from 1·3in. to 1·6in.

P. SUMITRA, *Moore.* Commoner than the preceding, but has the same habits. I have taken specimens in several places in Cashmere and in the Chumba State, in May and June, 1879. Expanse from 1·8in. to 1·9in.

Isoteinon, *Feld.*

I. MASURIENSIS, *Moore.* I took 6 specimens of this insect at Kotgarh this August, and have never met with it elsewhere. It frequents thistles and other flowers. Expanse 1·2in.

Thanaos, *Boisd.*

T. STIGMATA, *Moore.* Very common on thistles in Simla after the rains in 1878, and equally so at Kotgarh on the same flowers this year. Expanse 1in.

OFFICIAL PAPERS.

REPORTS UPON ARAKAN HILL TOBACCO,

CURED ON GOVERNMENT EXPERIMENTAL FARM, "MYOUNG."

LONDON, 1st April 1879.

BURMAH tobacco has never been before on this maket, and it is difficult to state if this growth will come in favour with our manufacture. The sample of long leafy tobacco shows a narrow leaf which is too thick and veiny to be fit for cigar purposes. The colors are mixed mostly yellow and grey, and this makes the leaf unfit for wrappers. The quality or the flavor of the tobacco is tolerably good. Value nominal 5½*d.*, to 7½ per lb. The short leafy tobacco is a little sandy, the leaf is, however, thick, and if this tobacco arrives here in a perfectly dry condition, it ought to find a good market here, value nominal 3½*d.*, to 5½ per lb.

It appears that the tobacco has not been *fermented* sufficiently, but that it was *shipped too early.* The general character and the quality of the tobacco are satisfactorily, and if plantation fermenting and packing are carried out in a careful manner, it would probably find a good market in England.

ROTTERDAM, 1st April 1879.

THIS tobacco is unknown here, but it has a certain analogy with the kinds from the "East Indies," "Calcutta," "Singapore," "and "Polah." My opinion of the same is not unfavourable, but it is difficult nevertheless to give any exact value because the tobacco is not known here. I think that this tobacco may be valued for this place from 15 cent. per ½ kl. (3*d.* per pound) more or less provided that the small leaf does not distinctly predominate. I think that the tobacco will find a market here, especially if the packing be well done, and if it is, if possible, cleared of the sand, which exists to a certain extent in the sample. Once well known here, it is very possible that it may have more value.

HAMBURG, 26th April 1879.

SEVERAL of our tobacco brokers, to whom I submitted samples for inspection, are of opinion that its value would range between 8 and 10 p.fg. (1¼*d.*) per lb. A leading broker, however, who has marked my sample, informs me that this tobacco has a certain analogy with that from Kentucky, which finds a ready market here in casks of 800. to 1,000lb., but nevertheless your tobacco should be much lighter (in both senses of the word) and the leaves considerably thinner to meet with anything like a demand.

The same would only be fit for smoking tobacco. This friend tells me further, that here it would only be worth from 20 to 25 p. fg. (3*d.*) per lb., and that he should not advice any great consignment for the present. Should the German Government, however, come to a satisfactory decision with regard to toboceo duty, then he would feel rather more inclined to speak for a small consignment, and he wishes to know whether the tobacco would be shipped in casks or bales.

(True Copy.)
W. G. HUGHES, MAJOR,
Supdt., Hill Tribes, Arakan.

SIR,—We beg to acknowledge the receipt of your letter of the 30th January and 7th instant, and to apologize for the delay in answering the same.

In reply we have to state that we have examined the tobacco forwarded us from the Myouktoung Farm in the Arakan Hill Tracts. We find the leaves to be of large size, good colour, but somewhat indifferent in cure and of an agreeable mild flavour.

This tobacco being unknown here, we propose to send the same to the Austrian Government for report of the Regie Office in Vienna, if permitted by you.

The value of the tobacco is uncertain, we estimate the same at 4 to 5 pence per lb. in bond, if shipped to England.

We, &c.,
(Sd.) ERNSTHAUSEN & OESTERLEY.

(True copy)
W. G. HUGHES, MAJOR,
Supdt., Hill Tribes.

REPORT ON THE ECONOMIC GARDEN AT SALARU,

FOR THE HALF-YEAR ENDING 30TH SEPTEMBER 1879.

HORTICULTURE sustained a severe check here from unprecedentedly severe hailstorms in the beginning of May. Fruit was in consequence a total loss. Besides the damage otherwise done to the trees, many of them were entirely uprooted or broken over a little above the ground. It will be years before the gardens in this vicinity be anything like what they were before the occurrence of these storms. Our wine crop which was estimated, would weigh about 100 maunds, yielded only 7 maunds and 9 seers of grapes, not a single bunch of which was fit to be seen on a dinner table. The plants have not yet got over the effects of the pelting they got just as the fruit had well begun to swell, and the leaves newly expanded, fresh, and in full action. It will be a long time before they fully recover. Pomegranates are the only fruit crop of any value this year in this neighbourhood.

2. EUROPEAN OLIVE.—Our plants continue to grow pretty well, considering the rough weather they had to put up with at the beginning of the season. None of the layers made from them succeeded; white ants destroyed the whole of them.

3. PEACHES and such like fruit trees are far from healthy. A number of them have died since the hailstorms, and still branches continue dying from those yet alive. I do not think any of them will fully recover. Where the bark had been knocked off by the hail; the branches of both peach and apricot are in many cases covered with gum, and show no sign of healing over.

4. DATE PALM.—We have several varieties of this plant, four plants gave fruit last year and were in flower this season, though the fruit did not come to maturity. One is a particularly fine large kind with a small stone, and one is equally good in flavour but of less size, the seed of both was sown and we have a number of young plants, probably each different from the parent. I do not of my own knowledge know that the Date will not grow true from seed, but the plant being diœcious, and the existence of so many varieties of it, tends to make one place very little reliance on this mode of propagating any fine or particular sort. I have been informed by people who have had a pretty lengthy experience in Date culture, that the only way of multiplying a favorite kind is by suckers, not seed of the old plant. We have both under trial here, and may be able to speak more positively on this subject a few years hence. The plant when young, throws up suckers more freely than after it has arrived at its full growth, some of ours have had as many as 8 suckers on them at one time, but this mode of increasing the number of plants is, even under the most favorable circumstances, a very slow process. The date is of slow growth, and takes a number of years care before it makes any adequate return for the outlay incurred in rearing a young plantation, but when once firmly established, it perhaps requires less expenditure of money or labour to keep it healthy, and in bearing order, than any other variety of fruiting plant capable of being grown in so dry a climate as Sind has. It succeeds well at Kotri and Sukkur, and so far seems to do well at Salaru. Its culture deserves to be largely extended.

5. The hail storms in the beginning of May killed all our Coffee plants.

6. INGA DULCIS (*Pithecolobium dulce*).—We have a large number of seedlings from 6 to 18 inches high. This plant makes an excellent live fence or hedge. I have seen some good specimens of it near Sukki, which had been raised by some one connected with the I. V. S. Railway. A few plants only have as yet been distributed, and they have been given to Europeans. Natives do not care to have them, in fact, they do not know the plant yet.

7. MAHOGANY TREE (*Swietenia Mahogani*).—After various futile attempts, we have at last succeeded in getting three young plants from seed received from Mr. Woodraw of the Botanic Gardens, Gunesh Khind; at present they are growing fast, and are quite healthy looking.

8. BAMBOO.—Some of the oldest plants here have this season, thrown up shoots nearly 7 inches girth near the ground, but the internodes are very short, and the *culms* taper so fast, that at 6 feet above the ground the largest specimen measures only 4½ inches girth. The atmosphere here is evidently too dry for successful bamboo growing. The plants I speak of are exposed to the full benefit of the hot south winds, if sheltered by tall forest trees, I make no doubt, but they would do better, but it is quite useless trying the plant in dry exposed situations. We have upwards of 2,000 seedlings of Bambusa Stricta on hand. This is a small variety, the *culm* of which is almost solid, and is according to Dalzell and Gibson, the variety from which boar spear handles are made. None of this sort has yet been distributed, but, if the young plants continue healthy, they will soon be ready to send out.

9. MESQUIT BEAN (*Prosopis Glandulosa*).—The plants of this, put into their permanent places last cold weather, have been yielding pods all through the present hot season, and, at the present time continue flowering, though a good deal damaged in May, the plants have grown fairly well, and are, to all appearance, healthy. So far this plant seems quite hardy and may be propagated by seed or cuttings of the ripe wood, the latter take root freely in February. A considerable number of plants have been distributed, and we have on hand fresh seed or young plants ready for any one who may require them.

10. CERATONIA SITIQUA (*Carob*). The plants are most of them healthy, but growing very slowly.

11. In addition to introducing fruiting plants, trees for shade, &c., we are endeavouring to encourage a taste for growing ornamental varieties as well. The generality of the gardens in Sind which have come under my observation are remarkably deficient in flowering plants of any kind. A good many varieties of flowering shrubs and creeping plants have been distributed during the past two or three years, the native garden owners do not pay much attention to them, for I find them generally in a corner out of the way or along a path already overcrowded with mangoe trees. Some plants fit for trellis work, such as Bougainvillea spectabilis, antegonon leptopus, Quisqualis indica, &c., may be said to grow to perfection here and are much admired, but I do not recollect of any of them having been asked for by natives, except for some of the Amir's gardens near Hyderabad. Flower-growing has not yet come properly into fashion in Sind, the generality of native gardens being little more than mangoe topes.

12. Most of the following economic plants, though properly belonging to the farm, have been kept in the garden as being more under control, both for irrigation and other attendance, the number of plants in each case being few.

13. GUINEA-GRASS.—We have but a small plot of this, but it is almost as well exposed as if it had been sown on the farm, being in an open space outside the garden reserved for vegetable culture. It has, in a manner been unfortunate, having been twice eaten down too near the ground by cattle; at present it is fully 6½ feet high, and beginning to shew signs of flowering. It bears transplanting very well; the area of our original plot has been doubled by this means and by dividing the roots. Should it seed anywise in proportion to its present appearance, the yield will be more than sufficient to sow half an acre next spring.

14. GROUND-NUT.—I have this year confined this plant to the vegetable ground, last seasons experience of it as a field crop, was enough to shew that under present circumstances it could not be grown in the open field. White ants are troublesome to it, otherwise it is growing remarkably well.

15. HULDI (*Curcuma longa*). This is also in the vegetable ground, and is thriving well.

16. CARDAMONA.—The plants are growing well but are protected from the hot winds by nim and other trees. This is a favorite plant with native garden owners.

17. We have several varieties of maize in the garden; seed has been repeatedly given to cultivators in this neighbourhood, but though it grows well with them, they do not try to save any seed of it for future planting, and sow only when we give them the seed.

18. Our chief garden work at present is weeding, transplanting seedlings, and putting down layers of different woody plants. Nearly all our stock of cuttings were destroyed by the hail storms in May, and nearly all our stock of young plants which were not killed, and were fit for destribution, have been disposed of; we have got quit this season of many plants which would have been considered too large for removal, had smaller ones been available; on account of the cost of carriage, people from a distance do not care to take very large plants.

19. I would beg that Government be asked to get us a small quantity of fresh seed of the Doum palm (Hyphœne the baica,) the Ginger-bread tree of Egypt. I believe it would grow with us, and I know of no other way of getting the seed fresh, than by troubling Government to oblige us by getting it.

20. The number of plants distributed during the past six months, were fruiting plants 902, roses 321, flowering of sorts 664, forest and shade-giving trees 195, shrubs 37, and pots of seedling flowering plants 19. Orders for seed are only now beginning to come in, the following number of packets have been sent out up to date, vegetable seed imported 109, ditto acclimatized 121. Flower seed imported 315, ditto acclimatized 199. Both plants and seeds have been given free in most cases. The local funds of Shikarpur and Hyderabad keep up this garden, and the inhabitants of the Collectorates are entitled to plants and seeds from it gratis. During the period under report very few plants or seeds have been distributed in the immediate vicinity of Salaru, most orders met have come from more distant parts of the country, and the cost of carriage in most cases prevents people from taking away so many plants as they otherwise would, of the fruiting plants and roses sent out this year, a camel could not carry over 15 to 20, and I have seen a lot leave, loaded with an average

of 10 plants each camel, so that though people get the plants at the garden for the carrying away, the carriage of them to any great distance, makes them somewhat valuable by the time they reach their destination. With the exception of January, February, and the beginning of March, plants cannot be successfully removed here without keeping a large ball of earth at their roots, even during these months, a Sindi would not run what he would consider the risk of losing the plants by shaking the earth all off their roots, for the sake of being able to carry a great number of them on one animal. We endeavour as far as possible to keep in pots a stock of plants for distribution, but (as as already reported) this year, the young plants intended for this purpose were almost all lost in the beginning of May, and the new stock raised since that time from seed and layers, will not generally be fit to send out much before March next.

21. On account of the fruit having been mostly all destroyed by the hailstorms we had in the beginning of May, the income from the garden will this year be very little. The pomegranates together with what was left of the orange and fig crops, have been sold for Rs. 200, and the sale of grain, &c., grown in the garden during the past six months will bring in about Rs. 100 more. The fruit crop however forms the chief source of our income; seeds and plants (on rearing which the greater portion of expenditure is incurred) are, in most cases, given away *gratis* and being no money return to the garden.

22. During the inundation season two persian wheels (Nars) were kept at work on the farm kurria, day and night, to secure a good supply of water for the garden. The ground round the trees were weeded and stirred up whenever it seemed to require it, so as to give the plants every possible chance of recovering from the effects of the storms in the early part of the season.

23. This season we have another new lot of *purdasee* coolies. They generally stay with us till they become what one might call handy garden laborers, when they leave and put themselves out as gardeners. Some of our late hands are so employed in this district at the present time.

SELECTIONS.

ARTIFICIAL MANURES AND PRODUCTION.

IT became too much the fashion in Ceylon a short time ago to decry artificial manures as more injurious than beneficial to coffee; now apparently the swing of the pendulum is going the other way, and cattle establishments for manuring purposes are being broken up on all sides. We trust planters will refrain from going to either extreme; there is no doubt that a great deal of money has been injudiciously spent over cattle, just as large sums have gone in artificial stuff that probably was not worth the cost of transport. Nevertheless what artificial manures can do for a tropical colony is well shown in the following extract:—

"The small Island of Mauritius, covering only about 700 square miles, spends annually from £200,000 to £250,000, mostly in raw and dissolved Peruvian guano, by the aid of which it is able to produce more than 100,000 tons of sugar, worth from £2,500,000 to £3,000,000, thus about 10 per cent. of the value of the produce is spent for artifiicial manures. British Guiana (Demerara) producing annually about 100,000 hogsheads of sugar worth about £2,000,000 consumes not less than from £100,000 to £120,000 in manure (principally dissolved Peruvian guano) every year, *i.e.*, about 6 per cent. of the value of the produce."—*Ceylon Observer.*

URINE MANURE.

M. RAOUL BRULLE has come forward with a new method of treating the urinous portion of town sewage in preparing it for manure, for which he claims numerous advantages over those hitherto in use. The oldest system is probably the Flemish, which consists in conveying the excreta away from the towns and storing them in large masonry tanks with the addition of water. In Paris the sewage is deposited at La Villette, thence to be directed by machine power through a long conduit to Bondy, where it lies in pools to ferment. In this manner its urea is transformed into carbonate of ammonia, from which the sulphate is obtained by distillation, while the solid matters are compressed and dried, and these sold as "poudrettes." Another system is the direct application of the urine to the irrigation of the soil, as practised on the plain of Gennevilliers. All of these processes are attended with grave inconveniences. 1. The system of fermenting for three or four years to convert the urea into carbonate of ammonia is extremely unprofitable from the length of time it occupies, during which the capital involved is producing no interest. 2. Masonry cisterns and tanks are very costly if made impermeable, as they ought to be. 3. The emanations from them are a source of annoyance and disease. 4. The cost of distillation and conversation of the disengaged ammonia into sulphate is considerable. 5. The drawbacks of the direct irrigation system are well known. The inhabitants protest against the nuisance, and the accumulation of putrid emanations infects the soil. From all these disadvantages M. Brulle contends that his system is free. It is based on the one hand, on the property of plaster to absorb, and thus reduce to a solid form large quantities of urine; and, on the other, on the greatly increased quantity of fertilising matter which can be introduced into the medium, by subjecting the plaster to repeated saturations, and driving off the superfluous moisture after each operation by means of hot air. In this way a solid manure can be obtained containing 5 per cent. of nitrogen and 1 to 2 per cent. of phosphoric acid, rich in fertilising elements, easy of transport, and containing not only five times as much nitrogen and phosphoric acid as fresh urine itself, but also all the mineral salts of the urine, which have a certain manurial value. The plaster itself also increases such value. In this system, therefore, interest upon capital is constantly accruing, instead of the latter lying idle for years, for the urine can be treated by it at once and the produce is ready for sale in a very few days. In addition to these economic advantages the process is absolutely free from all objections upon sanitary grounds.—*Home and Colonial Mail.*

ARTIFICIAL MANURES.

THE text of M. Ville's valuable and suggestive work is illustrated by a series of very striking illustrations which add force to his conclusions. As a frontispiece he gives a coloured sheet showing "The power of production of the chief systems of cultivation in their historical order." First we have "the pastoral system" in which a thin strip of "barley crop is added to a large grazing ground for cattle. Next comes "the Irrigation system" by means of which crops of all kinds were and are raised in Egypt. We then have an illustration of "the triennial system" where half the farm is devoted to grass for cattle feeding while the other half shows in succession :—

Wheat.
Fallow.
Wheat.

Then follows the class of "Rotation systems." First "continual rotation; stable manure only used." In this case 60 per cent of the area of the farm is devoted to cattle feeding, 50 per cent. being down in grass and 10 per cent. in clover. Crop, in this case followed each other in the following order :—1 potatoes, 2 wheat, 3 clover, 4 wheat, 5 oats. Next comes the coloured diagram of "continual rotation with manufacturing crops: stable manure only used." Here 70 per cent. of the land is devoted to cattle feeding, *viz* :—

50 per cent. grass,
10 „ „ swedes.
10 „ „ clover.

The crops in this case run (France, of course being the scene of the cultivation) 1 sugar beet, 2 wheat, 3 clover, 4 wheat, 5 oats.

All the foregoing, except of course the irrigation system, are quoted as most unfavourable and most unprofitable contrasts to the system which, by means of a copious use of artificial manures, M. Ville has inaugurated at Vincennes, the naturally poor soils of which are made to yield large and profitable crops year by year. M. Ville calls his new system "Free and continual rotation: stable manure mixed with chemical manure." The coloured square for this system is, like that devoted to the irrigation system, without any sub-divisions. We have instead the words :—

"Absolute freedom
Meadow or arable.

The crops are double those grown on the other systems."

By the words "meadow of arable," is, of course meant, that by the new system either the whole or part of a farm can be devoted to meadow for the profitable feeding of cattle, the meadow land being heavily manured with suitable substances, and the cattle fattened with substances, other than the grass or clover. But although in such cases the cattle manure may be utilized, its effect being enormously increased by the addition of chemical manures, the object is not to grow grass, &c., to feed cattle *for the sake of their manure.* It converting the whole of the land into arable is deemed the better and more profitable course, byre and stable manure can be entirely dispensed with, and maximum crops obtained by the use of four substances applied according to what is found to be the dominant principle of the particular plant. The four substances required, sometimes the whole of them and sometimes only three or even two, are, as we mentioned in our previous article :—

Nitrogen.
Phosphoric acid.
Potash.
Lime.

Now, judging by the composition of the ashes of the bean, potash ought, we suppose, to be regarded as the dominant principle in coffee. But before

preparing a manure for coffee, M. Ville would inform himself of the composition of the soil to which the manure was to be applied, and he would learn that on young estates, such as those of Dimbula, Dikoya, or Maskeliya generally, there was a considerable store of potash derived from the forest burnt on the ground, in the clay of the soil, and in the gradually decomposing felspar of the rocks. M. Ville, who distinctly recognizes the value of clay as a receptacle of potash, would, we suspect, join Mr. Hughes in stating that for soils like those we have alluded to, the application of potash was not so much needed as t reatment, such as forking and liming, which would render the stored up potash available. We are bound, however, to add, that the French writer makes light of the popular argument in favour of cattle manure as improving the *mechanical* condition of the soil. He contends that much larger crops and more profitable are obtained by means of artificial manures, the mechanical condition of the soil being improved otherwise—by careful culture of course. By the carbonaceous matter contained in cattle manure, M. Ville would, and probably with justice, set little store, seeing that plants derive the large proportion of carbon of which they are composed (nearly 48 per cent. in the case of wheat), from the atmosphere. Indeed, when we add together the constituents which plants derive from air and water, the remaining balance is very slight as a percentage. But even fractions of certain substances, phosphoric acid, for example, are of enormous importance. We can feel as we read this book that it is not so much nitrogen and potash, as phosphoric acid, lime, and culture which *young* coffee estates need, as Mr. Hughes pointed out. In the case of old estates, or young ones after they have borne several heavy crops, however, the dominant principle in the crop removed must certainly be supplied. If we are to judge by the ashes of the coffee beans, the dominant element (50 to even 55 per cent.) is potash. Now let us see what are the combinations which M. Ville advises to be used in the case of plants, the dominant principle of which is potash. For potatoes and flax his normal manure is composed of

	lb. per acre.
Calcic superphosphate	352
Potassic nitrate	224
Calcic sulphate	264
	880

That for vines and fruit trees, would, no doubt be more suitable for coffee, *viz* :—

	lb. per acre.
Calcic superphosphate	528
Potassic nitrate	440
Calcic sulphate	352
	1,320

This is nearly 11 cwt. per acre of substances which (even the gypsum) would be costly on coffee estates. In both the above cases the amount of nitrogen contained in the potassic nitrate is considered sufficient in addition to what is derived from the air and rain. But for vines and fruit trees there is a "Homologous manure," being the same composition as the normal manure, only that the potassic nitrate is replaced by a mixture of potassic chloride and ammonic sulphate, thus :—

	lb. per acre.
Calcic superphosphate	528
Potassic chloride at 80°	440
Ammonic sulphate	308
Calcic sulphate	44
	1,320

Potassic chloride has the advantage of being cheaper than the nitrate. It is composed of potassium 52·41 per cent. and chlorine 47·59, the first named constituent being equal to 63·16 of potash. The price of this substance when M. Ville wrote was 7*s*. 2*d*. to 8*s*. per cwt., against £1 4*s*. for the nitrate. To Ceylon planters it will be important to learn, that "since the discovery of the Stassforth mines, the price of this salt cannot fluctuate much, as the supply exceeds the demand." We believe there have been some importations of this valuable source of potash into Ceylon, by an estate agency house, but we have not heard the result of their experience. Ammonic sulphate is mixed with this substance, no doubt to supply nitrogen. Once again we have for vines and fruit trees a normal homologous manure where calcic superphosphate is replaced by *precipitated* calcic, thus :—

	lb. per acre.
Precipitated calcic phosphate	220
Potassic nitrate	440
Calcic sulphate	220
	880

The merits of precipitated phosphates are its greater cheapness, its more certain action, superphosphate being rather too soluble for newly-opened lands.

What puts fruit on vines, would, we should think, put fruit on coffee trees and by his manure M. Ville obtained a heavy crop, while vines left unmanured yielded absolutely nothing. This case is strikingly illustrated by engravings of the contrasted plants. But as our new soils at least are fairly supplied with nitrogen and potash, perhaps we had better look at the composition of the manures which M. Ville recommends for plants in, which the dominant ingredient is supplied by calcic phosphate, such as maize, *sugarcane*, sorgho, and Jerusalem artichoke. The normal manure in this case is composed of :—

	lb. per acre.
Calcic superphosphate	528
Potassic nitrate	440
Calcic sulphate	352
	1,056

And if a normal stimulating manure is required, 58 lb. of ammonic sulphate is substituted for an equal quantity deducted from calcic sulphate. It will be interesting to our readers to hear that M. Ville prefers to apply the lime in his manures in the shape of gypsum. He states :—"Calcic sulphate is nothing more than unburnt plaster of Paris, and is composed of sulphuric acid and lime. It is found in Nature in large quantities in the form of hydrate :—

	per cent.
Sulphuric acid	46·51
Lime	32·56
Water	20·93

Exposed to a temperature of 248° to 266° F., it loses its water and passes into the state of anhydrous sulphate, more commonly known as plaster of Paris. In using calcic sulphate, I prefer it in this state. It is worth about 8½*d*. per cwt. It can also be used in the form of raw gypsum, only in this case the proportion must be increased one-fifth." Of course gypsum is not likely to be obtained in Ceylon for less than many times 8½*d*. per cwt. But we suppose if sulphuric acid were available, the lime from burnt coral cou'd easily be converted from a carbonate into a sulphate? So many things are waiting to be done, when sulphuric acid is locally manufactured and cheaply as well as plentifully supplied. We could then for ourselves convert bones into calcic superphosphate, the most valuable ingredient (though not the most costly) in all manures. M. Ville expresses his intention to write a manual for the instruction of cultivators in this process. Meantime M. Ville is of opinion that the price of calcic phosphates is more likely to fall than to rise ; looking at the fact that they (bones apart) enter into the composition of all eruptive rocks. He alludes to the large deposits in Estremadura in Spain containing 70 to 80 per cent. of calcic phosphate. In Canada, Sweden, and in France, there are also deposits. After noticing the process by which calcic phosphates are converted into superphosphate, preferable generally on account of its superior solubility, M. Ville proceeds to notice exceptions in which bi-and tri-calcic phosphates are more beneficial, *viz., newly cleared land* and damp meadows. Our readers will notice that M. Ville does not apply nitrogen in the form of oil cakes, so largely used in Ceylon. He, however, fully recognizes the value of such substances, *if entirely deprived of the oil, which has no manurial value.* If cakes contain any oil he gives directions for extracting it by means of chloroform, or by carbon bisulphide, or the light petroleums or coal oils. He writes :—"These cakes are, in fact, very rich in nitrogen, phosphates and potash. Dissolved in water we can by their aid prepare from them a sort of artificial urine, which if thrown into the manure pit effects the disintegration of the haulm husks, and more especially the straw itself." This may afford a useful hint with reference to the maturing of composts. But we must close this article by giving the very heart of M. Ville's system. "The question then is," he says, "*can we, with chemical manures, cultivate the same soil with uniform success? Yes, we can, but always on two conditions*:—

(1) "Return to the soil by the aid of manure *more* calcic phosphate, potash, and lime than the crops have taken out of it.

(2) "Restore to the soil about 50 per cent. of the nitorgen of the crops. I say about 50 per cent. because there are certain plants which require less, while others, leguminous plants for instance ; seem to be able to do without any nitrogen being returned to the soil. We have already stated that part of the nitrogen required by plants is derived from the air, while some plants draw it more particularly from the soil.

"With respect to the calcic phosphate, potash and lime, the quantity restored must be in excess of that which is lost, because it is exclusively from the soil that plants draw them, and we must not only give compensation for the losses brought about by each harvest, but also fore those which are due to the solvent action of rain."

The bearing of these principles on coffee and other culture is obvious. We have to find out, in the case of coffee what constituents are removed in crop (parchment skin as well as clean beans), and no doubt we must make allowance to some extent for prunings and handlings, and to a large extent we fear for foliage lost by leaf disease. In this connection we must call attention to Mr. Cochran's letter in another column, and we shall recur to the consideration of the subject in a subsequent notice of M. Villes book.—*Ceylon Observer.*

"DRUNK-GRASS."

IT appears that the genuine good name of the Grass family for innocence and sobriety does not extend to all its members. There is a "drunk-grass," so called by the Dutch colonists a species of Melica, which in some parts of South Africa "intoxicates" cattle to an alarming extent, and the evil is spreading with the increase of sheep-farming ; the sheep, we believe, sorting out the other grasses, while they totally abstain from this.

The account is given by Dr. John Shaw in the *Journal of the Linnean* Society, Vol. 14. In Trimen's *Journal of Botany*, Dr. Hance—a well-known botanist resident in China—describes another grass, a new specie of Stipa from Mongolia, which intoxicates horses. A French Roman Catholic missionary and his party, making an excursion into the Aladian

Mountains, north of the Great Wall, one morning found their horses dreadfully debauched—indeed quite *horse de combat*—through partaking freely of this grass. On appealing to a family of Mongols encamped in the neighbourhood, the missionary was told that the proper antidote was vinegar, followed by a broth made of a goat's head. No vinegar being at hand, the missionary administered sour milk as a substitute, while the goat's head was cooking, the broth completed the cure, and the party returned safe and sober to Pekin, bringing some of the grass which Dr. Hance christened Stipinebrians. The intoxicating and poisoning of cattle, horses, and sheep, in California and Nevada, is said to be caused by some species of the Pulse family, which generally is thought to be as harmless as grass.

AGRICULTURE IN BARODA.

WE have been favoured with the following abstract of a lecture delivered at the Agricultural Show recently held at the Gaekwar's capital :—

Sir,—Not having yet seen in print the lecture delivered at the Agricultural Show held at Baroda the other day, I shall here mention a few of its salient points as they should be brought to the notice of different governments and the agricultural public in general. The lecturer was Mr. Dinshaw Ardeshir, the Municipal Commissioner at Baroda, and he spoke on the present agricultural distress and the practical measures needed to ensure the prosperity of that industry in the future. I quote these points from memory.

Mr. Dinshaw spoke enthusiastically, praising the effective countenance rendered to the show by the Agent to the Governor-General and the Minister of the State and the efforts of Major Nutt, which had brought this novel enterprise into existence at such a place as Baroda. He expressed a hope that the institution may be continued every two or three years, for it was well calculated to stimulate some of the more important agricultural pursuits which brought plenty to the country. Omitting the technical instructions which the lecture contained on the subject of the composition of soils, various products and manures, meteorology, &c., &c., I come to the practical remedies pointed out by Mr. Dinshaw as necessary to ensure the future prosperity of agriculture in India.

He was of opinion that beyond what has been devised in the very humane bill of the Hon'ble Mr. T. C. Hope, not much could be done to sustain any longer the ordinary class of cultivators in India. Excepting certain portions, he said, as a class, they were doomed to extinction in the natural course of things. Those of them who are poverty-stricken, and whose estates have been much reduced, should either be bought up by the better class of landholders or the Government, or the latter should get patels and others to interest themselves in such transfers. This was a question of many important details which, as also the handling of them, would vary according to each set of cases. He said that an improvement would take place in the condition of these miserable classes, when they have been converted into well-paid labourers serving a class of landlords superior to them in all respects, for no capacity is now left them for any independent maintenance and improvement of their landed estates.

He considered that the system of public and private education in India now demanded large modifications. Almost every boy receives such an excess of vague and general education, that he becomes unfit for any definite and practical work when he enters life. After the attainment of elementary knowledge, a boy should at once be practically trained for any business or profession he may be intended for. Confining himself to this one branch of knowledge alone, *e.i.*, agricultural, he said what amount of useful training and learning a student could obtain. He (the lecturer) would have public bodies to introduce into schools, brief and practical treatises containing local information about various soils and products, &c., of each district, the different influences that are being constantly exercised upon each soil or produce, the facilities or difficulties which may exist for carrying on successful agriculture, the means of improving crops or introducing new sorts of crops, the trading and mercantile resources of the district, and so on. He would suggest to the Government, as also to the enlightened and well-to-do landholders to offer prizes to those who would supply useful information, or make practical suggestions on the above points, or who could produce agricultural improvements as a decided improvement on the present ones.

It was indispensably necessary, he said, that every distinct province, whether British or native, should have an extensive farm which could produce all such articles as are required for military, &c., purposes, and which are produced from the soil, these farms being conducted on the most improved methods, and which could furnish practical education in agricultural matters to the students of the district. These farms can be rendered self-paying by the Government indenting on them for the stores they required.

He asked the more enterprising of the landholders to visit England and other parts of Europe themselves, to study the resources applied there to promote fertility of land. He desired that either a Government or some of the landholders should induce intelligent and experienced cultivators themselves to visit Europe, with a view to obtain insight into agricultural matters there. Again, he also would have the rulers and people in India to send for practical men actually engaged in agricultural pursuits from England, &c., and place them in charge of farms side by side with their practical brethren of this country. He said a European practical farmer would have to learn from Indian farms as much as the *khedoos* would learn in England, and if the former were trained and naturalized here, he could command a perfect indigenous knowledge which would produce the best of results that may be needed for agricultural prosperity.

He urged that landholders and others should start an agricultural association for each distinct province, not only to assist Government with the results of their researches, but also to render every practical assistance to farming. He said they very naturally formed one of the principal suppliers of public finances, and it was, therefore, their duty to aid the Government of the country by inducing a better adjustment and also every legitimate augmentation of land revenues, which are absolutely necessary for the progress and protection of the country. He did not think much of the cries raised as regards the incidence of land taxes. Though there are exceptions as adverse to moderate assessments, the real and principal evils which have brought about the present extensive depression in the country, are the natural outcome of the increasing population of the country, and the advancing stages of corruption which cannot but attack a peasantry divided among themselves, and who have been unable either to maintain or augment their original resources with the increasing demands or dissipation of the times. While he deplored the exasperating effects on the youths of the country which the present system of education produced, he hoped that vigorous measures may be employed by both States and peoples to render public education more of an individual and business-like character than it now can be said to be ; and he did not know why, when the difficulties have been met in the pointed and earnest spirit above indicated, the Indian soil could not better sustain the public administration, or produce as great a fertility as it did in old times when the world possessed much less experience than now. In conclusion, he added with much confidence that, under the matchless and benevolent auspices of the British Government, far better days were in store for India both for the maintenance and comfort of its immense population, as also in the interest of its export and import trade, all of which proportionately indicate the well-being of a country.—*Times of India.*

CULTIVATION OF THE AUSTRALIAN BLUE GUM IN CEYLON.

WE fear our correspondent "Eucalyptus" gives us credit for more personal knowledge of the subject he refers to than we possess. Our experience has certainly not been much more favourable, if so much so as that of many of our neighbours. Occasionally every one, nearly, of a set of plants put out will grow, but frequently a very small percentage will live, especially if the plants are allowed to grow big. When they do grow, the trees stand wind better in stiff soil than they do in the loose soil near walks,—that is when exposed to wind. In such positions, there seems nothing for it, but to put *two* large long stakes slanting inwards to each tree from south-west and north-east. The tree seems naturally to have little tap root, but we have seen one from which the earth had been cut away buttress itself by a tap-root rivalling the trunk in size. The seed seems to grow readily, spread over an unsheltered bed and watered when the weather is dry. Transplanting is the difficult matter, and we should recommend balls of earth and temporary shading. Better go to this expense than lose set after set of plants. But we once published an account of Colonel Beddome's process. It was to cut the bamboo of which estate baskets are made, and which is not more than an inch or two in circumference, into bits about three inches long. Place these pieces end ways close together, in thousands ; cover over with forest mould or fine soil and sow your seed. In this way there will be from one to three or four seedlings in each bit of bamboo. When carried out in the bits of bamboo the best plant can be left, the others being removed and utilised immediately or at a subsequent period. Perhaps planters with more experience will give our readers the benefit of their information. A new interest attaches to the cultivation of the Eucalypti as breakwinds or separately, from the fact that the fine straight timber makes excellent sleepers for railway inclines where hard wood is desiderated. The trees, many of them, are well grown at eight to ten years old.—*Ceylon Observer.*

IRRIGATION.

THE following letter has been addressed to the Editor of *The Argus* :—

Sir,—I wish to place at your disposal the results of some experiments in irrigation, made by me in the course of the past summer. I tried grasses only, of various kinds, but the only one that answered my expectations was prairie grass. My chief objects were to ascertain—1. Whether water applied during the heat of summer would answer. 2. The results to be obtained in the quantity of produce in the shape of hay. 3. The quantity of water necessary per acre, and the intervals at which the water should be applied. I shall only give the general results, premising that the experiments were carried out on too small a scale to enable me to ascertain what the expenses would be per acre if on a larger scale, and that the ground, though a strong soil, was of so stiff a nature that I had to give up attempting growing potatoes or other roots and vegetables in it.

1. I found it perfectly feasible to apply water at any time—day or night, in hot sunshine or on dull days—with advantage, so long as the grass was not submerged. There was no baking of the soil after drying, partly, I think on account of the nature of the grass, which threw its numerous roots near the surface.

2. I cut six crops of hay, the first on November 28, and the five succeeding crops at intervals of about four weeks, the last being on April 19. Prairie grass is a very succulent kind, and appears to contain much saccharine matter, which rendered the saving of the last crop somewhat difficult. These crops averaged 36 cwt. per acre each, or a total of nearly 11 tons per acre. I valued the hay at £3 per ton, or £33 in all. Although I cannot give the cost of the necessary preliminary work, and the wages of workmen, &c., still, if any considerable extent of country could be placed under irrigation, I think some very striking results could be accomplished. My own belief is that £10 per acre profit may be possible. I feel bound to express the opinion, however, that there are very exaggerated views held of the quantity of land available for irrigation, if the water is to be led over it by simple gravitation, without the aid of machinery.

3. I found that about 13,000 gallons of water per acre were necessary every fourth to sixth day, according to the weather. There was little or no waste of water as applied by me, but I applied more than was actually necessary, and I think that in experiments on a larger scale 15,000 gallons per acre, applied every four days, would be abundant, and allow a large margin for loss from various causes.

DACCA AGRICULTURAL SHOW.

THE annual Agricultural Exhibition came off with great *éclat* on the 1st of January last. This being the second year of the institution, we naturally expected that the philanthropic efforts of Nawab Assanoollah, Khan Bahadoor, will be appreciated and sympathised with by the other zemindars of East Bengal, and that they would co-operate in such a grand scheme to improve the natural products of the soil, in which every zemindar ought to be interested. But we were surely grieved to find that almost everything presented in the exhibition, came from the extensive estate of the Nawab, and that the other zemindars had not shown the least interest to promote such a laudable undertaking. But in spite of all these disadvantages, this second exhibition was decidedly an improvement upon the first, and we can commend the efforts and sacrifice of Nawab Assanoolah in such a noble cause in no measured terms.—*East.*

THE SYDAPET AGRICULTURAL SCHOOL.

THE Board of Revenue lately submitted to Government, letters from the Superintendent of Government Farms, reporting the falling off of applications for admission into the School of Agriculture, requested permission to postpone the entertainment of a new class till April 1880, and suggested the advisability of holding out to certificated students some prospect of obtaining Government employ in the Revenue Branch of the service. In their "order thereon," the Government state that they are not prepared to adopt the Board's recommendation for the continuation of the inducements to enter the School of Agriculture hitherto held out to the public. The reduction of the scale has, no doubt, had some influence on the number of applications for admission, and this was anticipated, but other causes have probably been at work. The time allowed for sending in applications was altogether too short, and the establishment of a scheme of agricultural education in the Bombay Presidency will have prevented the entry of students from that part of India, which contributed to the earliest class nearly one-third of its numbers. The Government would have been prepared to admit the applicants to a fresh class, but, as its formation has been postponed with the sanction of the Board, endeavours should be made to induce zemindars throughout the country to send pupils to the class to be entertained in April next. The Government think that pupils might also attend from such of the estates under the management of the Court of Wards as are in a position to pay for their support.—*Madras Times.*

THE FOOD OF PLANTS.

I.

THE following paper by W. Ivison Macadam, F.C.S., &c., Lecturer on Chemistry, was, as we briefly noticed a few weeks ago, read with much approval at a meeting of the Scottish Horticultural Association :—

To the several members of this association no subject can be of greater importance than 'plant food.' It matters not to which branch or section of the great army of 'tillers of the soil' to which each member belongs, for to one and all the subject we this evening consider must have interest.

In the higher section of landscape gardening, the planting or laying down, in fact the head work or thought element necessary for the raising of those beautiful and often costly Edens one finds scattered over our country, no subject can command greater attention than the nature and condition of the soil ; or, if we consider the practical part, the working of the ground, what can be of more use than a knowledge of the composition of the soil, and of the plant most suited to the ground, along with an idea of the ingredients necessary to the life of other plants the gardener may wish to grow, but the food of which his soil does not contain, and which he must therefore add so as to insure success for his crop.

Without further introduction then, let us consider what is necessary for the life of a plant, and also how we can supply these wants.

Take then as the first example, a tree or herb growing in all its Native grandeur, planted where it stands by that ever successful gardner 'Nature.' You find that the plant grows seemingly without effort, it is born, increases in size, and attains a good old age, according to the species to which it belongs, then dies, and falls where it has stood. New plants rise and take its place, to die in their turn. All this has gone on regularly, ceaselessly—and quietly from the first of time, and will go on until man steps in and breaks 'Nature's balance.

Let us suppose that man has now arrived on the scene. He no sooner sees the noble tree or the waiving golden grain, then he commences to remove from the soil her stores, carts off to feed himself and his dependants the grain, and fells the tree to build his house with. Go back to the spot after some years, and you will find that the soil, which on your previous visit yielded its abundance, now gives only a very small crop, and what it bears is thin and poor. How does this come to be?

Look back again to our 'native' tree, and learn what it is built up of. Take a portion of the plant and weigh it, then cautiously and slowly dry it, and reweigh, when you will find that only a portion of what you started with is left behind, that your piece has lost much of its weight. Whatever kind of plant you are working with, much of it has disappeared. The loss in weight consists of *water*, which grains contain from 13 to 14½ per cent. of ; peas, haricot beans, and lentils from 14 to 14½ per cent.; whilst in root crops, the amount runs up in potatoes to 75 per cent.; artichokes, 80 per cent. ; and in turnips, to 93 per cent. of the total weight. A large part of plants, then, consist of water.

If the residue after drying be now burned, and the ash left behind weighed, there will be a loss of weight, which is due to the burning off of the *organic constituents* of the plant. The amount of these organic compounds depends much on the class of plants worked with. In grains there is from 83 to 84·5 per cent.; in pease, 82½ per cent.; in potatoes, 24 per cent.; in artichokes, 19 per cent.; and in turnips, 6·4 per cent. of the fresh bulb.

The ash left after burning is composed of mineral matter, and amount in grains to from ½ to 2½ per cent. ; in peas to 3 per cent. ; in potatoes to one per cent. ; and in onions, to ½ per cent.

The proportions of these three constituents—water, organic matter, and ash or mineral matter—in some of the more common crops, are contained in the following table :—

	Water.	Organic matter.	Mineral matter.
Wheat	14·5	83·8	1·7
Rice...	14·6	84·9	0·5
Peas	14·3	82·7	3·0
Haricot beans	14·0	83·1	2·9
Potato	75 0	24·0	1·0
Turnip	92·8	6·4	0 8
Carrot	89·0	10·0	1·0
Beetroot	82·2	16·9	0·9
Artichoke	80·0	18·9	1·1
Onion...	91·0	8 5	0·5

The water is obtained from rain; the organic constituents part from the soil and part from the atmosphere ; whilst the mineral matter is derived from the soil in which the plant grows.

In its *natural*, or free state, the plant builds these different substances up in its structure, and on dying returns them once more to the storehouse from whence they were obtained to be again used by succeeding generations.

Man, on the other hand, removes the crops from the ground, and in this way, by slow degrees, impoverishes the soil, each year rendering it more and more unfit to sustain the life of the plant, which is therefore gradually reduced in size and quality until such time as the ground contains so little of the 'plant food' as to render it barren and unproductive. The following table gives the percentage composition of the ash of certain crops :—

Percentage Composition of the Ash of Plants.

	Potash.	Soda	Lime.	Magnesia.	Oxide of Iron.	Phosph. Acid.	Sulph. Acid.	Silica.	Chlorine
Wheat grain ..	23·7	9·1	2·8	12·0	0·7	50·0	0·3	1·2	—

Barley straw ..	9·2	0·8	8·5	5·0	1·0	3·1	1·0	67·8	0·6
Oats grain ..	26·2	—	6·0	10·0	0·4	43·8	10·5	2·7	0·3
Oats straw ..	19·1	9·7	8·1	3·8	1·8	2·6	8·3	48·4	3·2
Beans ..	33·6	10·6	5·8	8·0	0 6	38·0	1·0	1·2	0·7
Potatoes ..	55·7	1·9	2·0	5·3	0·5	12·6	13·0	4·2	4·2
Turnips ..	41·9	5·1	13·6	5·3	1·3	7·6	13·6	7·9	3·6
Hay ..	18·1	1·3	23·0	6·8	1·7	6·0	2·7	37·8	2·6
Clover ..	35·5	0·7	32·0	8·4	0·4	8·4	3·3	3·4	7·0

From the above table it will be observed that the principal mineral constituents of plants are nine in number—potash, soda, lime, maugnesia and iron in combination, with phosphoric, sulphuric, and silicic acids, and with chlorine.

Before proceeding further let us consider separately the several mineral constituents of the ash of plants.

Potash contains the metal potassium (K), which is also present in nitre or saltpetre (KNO^3), in muriate of potassium, or chloride of potassium (KCl), and in kainit, as chloride along with the chloride of magnesium.

Soda has as its base the metal sodium (Na), which also forms a part of common salt or chloride of sodium (NaCl), Glauber's salts or sulphate of. soda ($Na2SO^4$), and nitrate of soda, or chilé, or cubical saltpetre (NaNO3)

Lime is a compound of the metal calcium (Ca), which also enters into the composition of chalk or carbonate of lime (CaCO3) and stucco, gypsum, or sulphate of lime ($CaSO^4$), and in bone it is found in combination with phosphoric acid as insoluble or bone phosphate ($Ca32PO_4$).

Magnesia contains the metal magnesium (Mg), which is also found as the base in Epsom salts or sulphate of magnesium (Mg SO^4) and as chloride of magnesium ($MgCl_2$) in kainit.

Oxide of Iron is a compound of the well-known metal iron with oxygen.

Phosphoric Acid is composed of the element phosphorous (P), in combination with the gas oxygen (O). Its principal state of combination is with lime, as bone phosphate (Ca_32PO_4) and as soluble phosphate (Ca^3PO^3 or $CaH42PO^4$).

Sulphuric Acid is formed of sulphur (S) and oxygen (O). It is found in combination with lime as stucco ($CaSO_4$), and forms the acid portion of Glauber's salt (Na_4SO_4).

Silica is made up of the elements silicon (Si) and oxygen (O). It forms what is known as sand, and with many metals forms silicates.

Chlorine is a yellow-green gas, and is found as a part of common salt (NaCl) muriate of potash (KCl), and chloride of magnesium ($MgCl^2$).

The principal organic constituents of plants are starch, sugar, dextrose, oil, gluten, legumin cellulin, and lignin. The amount in which these occur, will be observed from the following table :—

Table of the Organic Constituents of Plants.

	Wheat.	Barley (cleaned.)	Rice.	Indian Corn.	Peas.	Haricot Beans.	Potatoes.	Turnips.	Beet.	Carrot.
Gluten ..	11·0	6·2	7·5	9·0	—	—	2 3	0·5	0·4	0·5
Legumin ..	—	—	—	—	22·4	23·0	—	—	—	—
Strach ..	69·0	76 0	76·0	64 5	51·3	52·3	18·4	—	—	—
Sugar ..	—	—	—	—	—	—	—	—	10·0	4·5
Dextrose, &c. ..	—	—	—	—	—	—	2 0	4·0	3·4	0 5
Oil ..	1·2	1·3	0 5	5·0	2·5	2·3	0·3	0·1	0·1	0·2
Cellulin / Lignin ..	2·6	0·8	0·9	5 0	6·5	5·5	1·0	1·8	3·0	4·3
Ash ..	1·7	1·1	0·5	2·0	3·0	2 9	1·0	0·8	0·9	1·0
Water ..	14·5	14 6	14·6	14·5	14·3	14·0	75·0	92·[illegible]	82·2	89·0
	100·0	100 0	100·0	100·0	100·0	100·0	100·0	100·0	1 0·0	100·0

Starch ($C6H10O^5$) is a white body which softens in cold water and gives a semi-solution with hot water. The various crops yield starches which do not differ chemically, but the granules of which when seen under the microscope are very different in form and size.

Sugar ($C_{12}H_{22}O_{11}$) is found principally in the stems of plants, chiefly grasses (such as sugarcane), and a few trees (maple and date palm), and also in the tubes of beet and carrot.

Dextrose or *grape sugar* ($C_6H_{12}O_6$) is a variety of sugar principally obtained from the fruits of plants.

Oil. A very large number of oils are obtained from the vegetable kingdom, such as rape oil from rape seed, castor oil from the castor plant, cocoanut oil from the cocoanut, &c. Each has properties characteristic to itself, and some of them are very complex in structure.

Gluten is a white sticky mass obtained when flour is washed with water in a cloth. It is found in largest quantity in the cereals.

Legumin is obtained chiefly from peas, beans, tares, and other plants of the same order.

Cellulin and *Lignin* form the bones of the plant; the first being chiefly found composing the walls of the cells, whilst the lignin constitutes the hard matter or woody fibre which is formed inside the cells.

These organic constituents are chiefly built up of the four elements—carbon, hydrogen, oxygen, and nitrogen.

Carbon is largely present in all plants, and can best be seen on charing a piece of wood, when the hydrogen and oxygen are driven off as water, &c., and part of the black carbon remains.

Hydrogen is a gas which has no colour or taste, is combustible, burning with a pale blue flame. It forms one ninth of all water by weight.

Oxygen is a clear, colourness, tasteless gas, which will not burn, but which supports combustion. It forms eight-ninths by weight of water, and one-fifth by volume of the atmosphere.

Nitrogen is a clear colourless, odourless gas, which does not burn, and will not support combustion. It is present in the atmosphere to four-fifths by volume of the whole, and is contained in sulphate of ammonia and nitrate of soda.

From the diagrams given, it will be seen that the greater number of elements necessary to plant life are obtained from the soil. All soils, however, have not the same composition, for all do not bear equally good crops. The soil must therefore very in composition. Some portions of the earth's crust are barren, and cannot raise any crops whatever. Examples of this are found in rocky places, where the material being hard, insoluble, and compact, does not allow of the plan roots finding their way below the surface and drawing their nourishment from it. Such rock may in time by the agency of frost and rain be disintegrated into very fine and fertile soils, but in the massive state must rank as barren and unfruitful. Other examples of this class are met with in sand and in alkali covered tracts of country, such as are found in Chilé and in some other countries. Fertile soils too are not all equally prolific, for whilst one field may be clothed with grain, another may bear only trees and a more favoured spot may be so thickly covered as to resemble jungle. No doubt climate has much to do with this but much also depends on the chemical and mechanical condition of the soil. The following diagram will illus'ate the more important classes of soil :—

Composition of Soils.

	Vegetable Mould.	Sandy.	Fertile Clay.	Loam.	Calcareous (Lime).	Marl.
Organic Matter ..	10·08	0·49	3·38	11·24	6·33	10·50

Carbonic Acid, &c..	—	—	1 87	—	—	—
	100·00	1 0·00	100·00	100·00	100·00	100·00

Soils then, vary much in composition, and all soils cannot therefore be equally good for growing all crops. A knowledge of the composition of the soil will aid the worker much, for, with a statement of the analysis of the ash of the plant he may desire to grow, he will be able to see in what his soil is deficient, and also which particular crops he can more economically grow with a fair prospect of success. The most necessary foods to be supplied to plants will be seen from the table to be phosphoric acid, lime, and nitrogen. With special crops the amount of each of these must vary.

It will be evident then, that if man removes the crops from the ground it is necessary that he should give to the ground an equivalent. This system of returning to the soil what is taken from it, is termed manuring and the material so applied is called a manure. A good useful manure is one which contains all the saline ingredients necessary for the life of the plant it is desired to grow. Such substances are known by the name of 'general manures,' and leave the ground after the crop is removed in a more fertile condition than before they were applied.

Farmyard Manure.—This was one of the most early applied manures. It consists of the old litter from stables; byres, &c., along with the solid. and part of the liquid excrements of the animals. It varies much in composition, the solids containing most of the earthy matters, whilst the liquid portion has the saline constituents in solution. Much, too, depends on the

care, taken in bringing or heaping the substance, so as to protect it from undue rain or damp, else the salts will be dissolved out, and, passing into the drains, be lost. The composition also depends much on the animal which produces the manure, as, according to Boussingault, you find in *horse urine*, nitrogen equal to 1·55 per cent., whilst in *cow urine* there is only 0·44 per cent. Then the earthy substances in horse dung equal 4·02 per cent., and in cow dung equal 1·18 per cent. It is a waste material, and as such may be used with advantage; but where it requires to be bought is an expensive manure; for, taking the material at 7*s* per ton, the present market price (cartage excluded), and putting 20 tons on the land per acre, the cost would be £7 (cartage excluded), whilst an equivalent amount of dissolved bones—namely 8 cwts.—would cost £3 4*s*, showing a balance of £3 16*s*. in favour of the chemical manure. Then again, as 20 tons will contain all the nitrogen necessary for a six years' rotation of crops, along with three times the amount of salts required, it follows that a lengthened use of this manure will tend to load the soil with saline matters. It is therefore better to employ the farmyard manure together with a certain quantity of some other manure.

(To be continued.)

MR. DECLOSETS ON ARTESIAN WELLS.

MR. A. DECLOSETS, C.E., wrote as follows to the Joint-Secretary to Government, Public Works Department, Irrigation Branch, on the 30th October last :—

"I have read in the newspapers your report upon artesian wells and on their application to irrigation or water-supply of towns, &c., and I ask leave to say that your own conclusions were perfectly right; but I will add that, as the data of the Chief Engineer in Pondicherry were established upon a work made by Government Departmentally (*en regie*), the cost per yard you have extracted from Mr. Carriol's report does not represent the true, and real expenditure incurred for boring the Colonial Garden's well; so that if such boring had been executed by a contractor or by private parties, the cost would have been greatly above that stated by Mr. Carriol for the sake of showing economical working. In fact, the cost of the Colonial Garden's well, in supposing the work done by the instrumentality of an Engineer or of a contractor, could be established as follows :—

	Rs.
Wages of workmen for four months	650
Value of eighty metres of piping	972
Transport and fitting charges	264
Shipping and other charges	430
Interest at 5 per cent. on the boring apparatus, the shear legs, and other implements, the value of which has been of Rs. 6,000	124
Superintendence and staff during four months' work	1,600
Total ...	4,040

The total depth of the well being 86 yards, 86 the cost per lineal yard is therefore in reality, say, Rs. 46. The well was bored under very favorable circumstances, as the spot where Pondicherry is built consist of an alluvium of detritic remains from the tertiary formation adjoining, and known as the 'red hills' of Pondicherry, and which is composed of sand, clay more or less indurated, gravels and rolled pebbles of quartz, calcareous nodules, and the like. No stratum of laterite or of conglomerate or sand-stone has been encountered, and it is easy to perceive that the work of boring was easy, and proceeding at the rate of nearly one yard, per diem, the cost was reduced to an average rate. I think that the cost stated for the Colonial Garden's well cannot be taken as a criterion. There are some few examples of cost of wells bored at my knowledge in and near Pondicherry. A well bored in the Savana mills at Pondicherry in the alluvium has cost, exclusive of superintendence and tools about Rs 2,000 for a depth of 56 metres, that is 61 yards, which gives per lineal yard Rs. 32·78. Another well in the same strata, at the "Oupallom mills," where water was tapped at 40 yards deep has been contracted for Rs. 1,500 (not accounting for apparatus and repairs); this gives Rs 37·50 per lineal yard. Another well, three inches in diameter, tried in a garden in the Pondicherry town, was abandoned after reaching 45 yards, for boring another of a larger section and after an expenditure of Rs. 780 about. No superintendence was accounted for, as the works were superintended by the proprietor; the cost of the lineal yard of this well has been Rs. 17·22. I was engaged in the beginning of this year for continuing the boring of an artesian well in the estate of a gentleman of Pondicherry, near the large tank of Oussaudon, 6 miles west of the sea. There the grounds belong to the tertiary formation, and its thickness is estimated at about 200 or 250 feet above the cretaceous formation underlaying, and into which cretaceous strata ascending waters sheets may by found very probably. This tertiary formation dips eastwards at an angle of about 2°, passing under the alluvium of the Pondicherry plain. The work previously done had reached eight yards through a stratum of yellow clay mixed with sand, rolled pebble of quartz, small irregular pieces of carbonate of lime, and had arrived upon a stratum of limestone, or a large boulder of such. This limestone, of yellowish colour and saccharoid was extremely hard to bore; we were at work upon it during two consecutive months, and had attained a depth of 15 yards when the proprietor stopped the work, thinking the cost too high for him. In this case no superintendence was charged, and the total expenditure, exclusive of tools, has been Rs. 334 as follows :—

	Rs.
My travelling expenses	60
Wages	80
Several sundries	60
Repairs and new tools	50
Seven yards of iron piping, 7½ inches	84
Total ...	334

The cost of boring has therefore been per lineal yard, s. 47·78. Lastly, a trial well I had bored in Madras at the then Napier Iron Works, through strata of blue clay and sands alternately reached at 30 yards an ascending water sheet of brackish water, above a stratum of a greenish kind of sandstone. The cost of this well, exclusive of superintendence, of tools, and of piping was about Rs. 100, which will give per lineal yard about Rs. 3·33.

All the above are data from practical operations. You could perceive that the rates differ widely. Now I will add, that I have a party of workmen under a Supervisor engaged in boring a well (artesian) in Madura, and that the rates I have agreed to vary from Rs. 30 to Rs. 50 per yards, according to the depth. The ground in Madura seems to me to consist of an alluvium of the Vigairiver, having filled up a granitic 'basin,' the depth of which I estimate at about 80 or 100 yards. This alluvium I think, must consist of *debris* from primitive rock, clay, sand, and probably strata of carbonate of lime kunker of not ancient formation. I hope to tap some water-sheet percolating the sand beds in the upper portion of the Vigai Valley, and running below above the granitic formation. I hope also that we will be fortunate enough so as not to come in contact with any boulder of gneiss. If this can be of interest for you, I shall be very glad to send you further on some particulars of that boring at Madura. I will, in ending, observe that the cost of boring artesian wells will also depend in great measure on the skill of the person entrusted with the work. It seems to be a general impression that nothing is more easy than to bore a hole into the earth; but this will be found a delusion, as has been the case in Pondicherry, and as experienced by several natives who have undertaken to bore artesian wells, without the proper knowledge and tools, but have ended in a failure detrimental to their customers. An artesian well is an expensive commodity which as you have explained, would not suit the native irrigation, but could be turned into some other mode of water-supply where the prime cost is not of a primary consideration."

The Madras Government have thanked Mr DeClosets for his communication. The Government will be much obliged for any further details of the artesian well which he is engaged in sinking at Madura.—*Madras Mail.*

NOTES ON A NEW FIBROUS PLANT.

AMONG the specimens of raw produce collected in Bombay for the Paris Exhibition were samples of fibre extracted from *Malachra rotundifolia* (so named in the list of Bombay contributions).

Regarding this specimen, the following remarks were made in a memorandum attached to the list of contributions :—

"From this plant, which grows abundantly during the rains in waste places in and near Bombay, Dr. W. Gray, M.B., extracted a fine fibre and sent it to the proprietor of the Bombay Hemp and Jute Mill for examination. It was most favourably reported upon. At the beginning of the last monsoons the proprietor was, at his own request, taken to the Byculla flats in Bombay and the plant was shown to him. He remarked that the usefulness of this plant was not known, and reported that the discovery is a boon to Bombay! He has subsequently taken steps in procuring fibre from this plant, and about forty day labourers were till now kept working by him at Chembud, a village near Coorla. A new industry has been started.

This fibre perhaps deserves special attention.

Struck with these remarks, I asked the officer who was in charge of the Bombay collections for Paris, and who had prepared the list (Mr. F. F. Arbuthnot, C.S., Collector of Bombay), to be good enough to furnish me with some further information on the subject, and samples of the fibre as well as of the plant itself. Mr. Arbuthnot was not able to send me any of the fibre, the whole quantity perpared by the mill-owner referred to above after the monsoon having been already exhausted. He had mixed the fibre with jute and made gunny bags of the mixture. Mr. Arbuthnot sent me samples of the plant, however, and copy of a letter from the mill-owner to Dr. Gray on the subject of the fibre. The letter was to the following effect :—"I have received through your friend, Mr. B., a sample of a nicely cleaned new fibre taken from a jungle plant, and being new it gave me extra pleasure in testing it, and I can safely say that the new fibre is quite as good as jute. If this new fibre can be grown in quantity, it will be a great thing and a boon to this presidency. The fibre is actually not the yarn of jute, nor do I know its true name. It seems like what the natives call sanee bhendee, or jungle bhendee, but even that is doubtful, as bhendee is scarcely so good as this fibre.

"The fibre is in length from eight to nine feet thoroughly cleaned from gummy substance and dirt, has a nice silvery appearance with a peculiar lustre, and is almost as soft as silk. In passing the fibre through the machinery damped with oil and water as is commonly done with Bengal and Konkan jute, yarn was produced strong enough and nearly equal to that made from the second quality Bengal jute. In the opinion of our European spinning master, owing to the almost imperceptible difference between the yarn made from the new substance and Bengal jute, it is very suitable for weft; but if the plant is carefully grown and well looked after, the fibre would then no doubt rank fully equal to Bengal and Bombay jute

Owing to the high prices ruling for jute in Bengal and elsewhere, the new fibre, if carefully prepared, would command a ready sale at Rs. 8-12 to Rs. 4 per Indian maund."

I submitted the specimens of the plant and the papers received from Bombay to Dr. King, Superintendent of the Botanical Gardens, Howrah, who had kindly offered to indentify and name the plant. He says that the plant is *Malachra capitata, not M. rotundifolia,* which is found only in South America, and he adds :—*Malachra capitata,* though probably originally a native of South America also, is now found everywhere within the tropics. It now grows sparingly about Calcutta, but as it is not mentioned by Roxburgh in his *Flora Indica,* it appears probable that it did not occur at all here in his time. Wight and Arnott do not mention it in their *Prodromus Flora peninsula Indiæ Orientalis,* and it is therefore improbable that it was common in Southern India when that book was written. I should not anticipate any difficulty about growing the plant in Bengal, but whether it would yield as good a fibre or be as valuable as jute, I am quite unprepared to offer an opinion. The plant belongs to the natural order *malvaceæ.* It is an erect annual (or occasionally perennial) shrub, covered everywhere with very stiff hairs. The leaves are broadly heart-shaped, almost rounded and are borne on long stalks.

The flower heads are also carried on long cylindrical stalks which rise from the axles of the leaves. The flowers themselves are yellow or white in colour. There are about five or six of them on each head, and they are sorrounded at their origin from the flower-stalk by three or four half-kidney shaped braces. Each flower produces five seeds."

The above is a popular description. Sir J. D. Hooker's description in the flora of British India is to the same effect, though stated in botanical terminology. Sir Joseph Hooker writes of this plant (*M. Capitata*) that it occurs " throughout the hotter parts of India from the North-Western Provinces to the Carnatic, probably introduced." The members of this family are usually found in marshy places within the tropics. It would seem, therefore, that this species would thrive well in Bengal. In fact, it is already common about Calcutta, and Voigt (*Hortus suburbanus Calcuttensis* p. 112) refers to it as domesticated in his time (1841) about Serampore. Mr. Blechyden tells me that Graham, in this Catalogue of Plants in Bombay and its vicinity, alludes to *Malachra rotundifolia* as introduced by Mr. Nimmo about forty years ago.

The preparation of the fibre is the same as that of jute. When Dr. Gray operated on the fibre in Bombay, he steeped the stem in water for a week. It must be steeped when freshly cut, for according to the experience of the mill-owner who tried the fibre, if the stem is exposed to the sun and allowed to dry, great difficulty is found in getting rid of the external bark, and the fibre obtained is coarse and inferior in quality.

The utilisation of this plant would be specially advantageous in the Bombay Presidency, where as yet attempts made to grow jute can hardly be said to have had any success. But the plant seems to merit attention in Bengal too. Growing as it does and flourishing without any attention in marshy soil, of which we have more than enough for all purposes in Lower Bengal, it would seem to offer to spinners and to paper-makers an excellent substitute for an addition to jute. I believe the Bally Paper Mills Company are anxious to find some fibrous product capable of conversion into paper at low cost. Here is one to their hand, and I beg to recommend it to their attention, as well as to that of jute spinners and rope and twine makers.

In Balfour's Class Book of Botany, p. 771, it is said that in Panama the leaves of this plant are used as an anthelmenthic.—*J. E. O'Connor.*

MINERALOGY.

GOLD-MINING IN THE WYNAAD.

WHEN we read of another company, with a capital of £100,000, being formed in London for working the quartz reefs in the Wynaad, there seems no fear of the mineral resources of this district being any longer neglected. Mr. Brough Smyth's visit to this presidency has certainly had the effect of calling public attention to a possible source of wealth in India which had hitherto been singularly neglected. It has been objected to Mr. Smyth's reports that they were not definite enough in their assurances of the existence of gold in payable quantities, but we feel bound to say that we think those objections hardly reasonable. After all Mr. Smyth could do no more than test the quartz found in certain localities, and form his estimate of the general character of the reefs from the samples he had examined. With the staff at his disposal, it would be impossible for him to make a detailed examination of the country over which gold-bearing rocks have been proved to exist. The important fact remains that, so far as Mr. Smyth's examination has gone, it has proved that gold does exist in certain parts of the Wynaad in quantities that would be considered highly encouraging to mining enterprise in Australia. It is a well-known fact than in the colony of Victoria the average yield of quartz gold is something under seven dwts to the ton ; while Mr. Smyth has found quartz in Mysore and the Wynaad yielding at the rate of several ounces of gold to the ton. " Ah, but these are only samples," say the sceptics. This is quite true, but it is fair to assume that the samples give a good idea of the general character of the reefs from which they have been taken. Judged by this standard, it is undeniable that the quartz reefs which have already been explored offer a fair prospect of being profitably worked. Much however will depend on the constitution and management of the Mining Companies, whether they will be financially successful or otherwise. We should say it would be absolutely essential that native labour should be employed. European or Australian labour would be too expensive, except for purposes of direction and supervision. The success with which the coal mines are being worked in Bengal and the Central Provinces, would suggest that there should be no insuperable difficulty in obtaining the necessary native labour for quartz mining, which is no more laborious or dangerous work than coal-mining. The necessity of having trustworthy European managers in charge of the mines and mining plant is obvious enough. In fact, a very great deal will depend on having honest and efficient supervision on the spot. The Government, too, will have their work to perform in connection with these gold mining enterprises, and must be careful to do it in a way that will not fetter or discourage the Companies.

Of the Company referred to in the telegram we know nothing as yet, but it is supposed to be patronised by some wealthy London firms who have taken over Messrs. Smith, Fleming & Co.'s interests in certain proprieties in the Wynaad. The Alpha Gold Mining Company has now entered on a new lease of existence, in connection with a Company in London that is to raise a capital of £50,000 for working the reefs that belong to the former Company. A third Company has been formed in Madras for working certain reefs that have been explored in Mysore, and which are said to promise a yield of gold equal to that found by Mr. Smyth in the Wynaad. There is now, therefore, a good prospect of gold-mining in India having a fair trial. Should these Companies succeed, they will have plenty of followers, and a very important step will have been gained in the direction of righting our exchanges with Europe. Should they fail, they will but share the lot of many other adventures of a like character. They will have proved, at all events, that India must still look to other countries, for her supply of precious metals.—*Madras Mail*

GOLD MINING IN SOUTH INDIA.

ADVANTAGE has been taken of the revival of enterprise in the London market to introduce the South Indian Gold Mining Company to the notice of investors. The capital is £100,000 in shares of £1 each, of which £33,000 is taken by the vendors. The concern is formed for the purpose of purchasing and working mining rights on 1,200 acres in the Wynaad, comprising "numerous reefs of auriferous quartz of great extent." Mr. C. J. Harvey, late manager of the Clunes Works of the Port Philip Mining Company, pronounces them to be "most valuable properties." It is remarked that the statements made during the last few years, and the very considerable interest excited in the minds of scientific men in respect of the gold deposits in the Wynaad, prompted the Government of India to institute an official inquiry into the subject, the result being to confirm the fact of the existence in this district of abundant deposits of the precious metal. It is well known that for years past, the character of gold mining has completely changed from what it was in the early days of California and Australia. What was then fairly looked upon as a speculation, has now become, by the introduction of machinery, a steady and legitimate industry, yielding regular and remunerative dividends. To effect this result, what is now looked for by experts is, not so much rich pockets of ore, as a plentiful supply of auriferous quartz, which will permit of continuous crushing, and give a fair return for all work done or money expended. This company expects to earn £30,000 per annum net, or 30 per cent. on the capital. A powerful company has been formed in Glasgow for the purpose of working extensive mining rights of a similar nature in the same district, and arrangements are contemplated for the co-operation of the two companies in the erection of works on a convenient site as regards water-supply, thus affording mutual support and economising expenses. Engineers, accompanied by one of the directors, have recently been commissioned to examine the properties of the Glasgow Company, and advantage was taken to obtain the examination by them of the properties now to be acquired by this company. It is in consequence of the report of these gentlemen that the Glasgow Company have decided to commence their operations on the adjoining estate, and it is on the report and information thus obtained from disinterested parties, that it has been decided to place the present enterprise before the public.—*London Commercial Correspondent of Times of India.*

FORESTRY.

TREES IN TOWNS.

AT the Social Science Congress, Manchester, Dr. Phene read a paper " On the Sanitary Results of planting trees in towns." He said that, during repeated visits to the Continent, he had directed his attention to the apparent difference of health of urban populations, in those parts where trees grew, and where they did not, and had always found those persons living in the vicinity of trees looking more healthy than their neighbours. He had closely observed what trees grew best in such confined spaces, and began his experiments in England as far back as 1850, by planting

several streets in the style of the French boulevards, in a neighbourhood which, though at a low level, was shown originally to have been quite healthy, but in which a number of small houses had for a long time back been erected, and in which houses fever and diseases of various kinds were frequent. The streets were in different positions, *i.e.*, from north to south and east to west. The result of his experience was, that quite independently on the condition of ill-health which often prevailed in some of the neighbouring districts, from which the occupant of these planted streets were free, the same thing applied to periods of epido—when the large and wealthy neighbourhoods around, but further removed, were also seriously affected. He did not of course attribute the whole of the difference to the trees. He had exerted care in drainage and other sanitary improvements with of course, beneficial results, but, on the one hand, the levels, subsoil, and exact position were shared by a large number of inhabitants other than those on the estate in question, and all the sanitary appliances and advantages were enjoyed by the wealthier neighbourhoods, and yet during thirty years he had not been able to trace a single case of fever or small-pox in any of the streets so planted, even when the epidemics were most serious around him, including the districts occupied by the wealthy classes. Dr. Phene then described the latest scientific experiments on the oxygenating property of trees from which most beneficial results were manifest, and from which it was evident that the presence of fresh green foliage was a prime condition in the health of a dense urban population. The following is a list of the trees which, from experiments extending over thirty years, he has found grow in London, some of the most beautiful being those which grow with great rapidity and little attention. Acer psudoplatanus ; Ailanthus glandulosa ; Catalpa syringifolia ; Fraximus Europea ; Gleditschia ; Populus alba ; Populus nigra ; Populus Caudensis ; Quercus cerris ; Rhus typhinum ; Robinia ; pseud-acacia ; Tilia ; Ulmus campestris ; also the common ash, oak, elm, pink chestnut, copper beech, (a fine specimen of which is in the rectory gardens, Chelsea), mulberry, thorn,—white and red ; common and oriental planes ; and of shrubs, Ilex ovata, and other hollies , lilac, common and Persian, Euonymus, various, almond and wild plum, privet, aucuba, &c.

THE GARDEN.

A PLEA FOR THE SUNFLOWER.

THE value of the sunflower, from an agricultural point of view, has frequently been pleaded of late, but nowhere do its merits appear to be so thoroughly appreciated as in Lithuania. According to M. Grunert, of Landeshut, who has recently published a paper on the subject, on his return from a journey to the province, the sunflower is there universally cultivated in fields, gardens, and borders, and every conceivable part of the plant is turned to some practical account. A centner of the seeds yields as much as 40lb. of oil, scarcely inferior to Provence oil, and the pressed residue forms a good wholesome food for cattle, as also do the leaves and the green stalks, cut up small, all alike being eagerly eaten. The fresh flowers themselves, when a little short of full bloom, furnish a dish for the table which bears favourable comparison with the artichoke. They contain a remarkably large quantity of honey, and so prove a great attraction to bees. The seeds are a valuable food for poultry, or supply fine groals of a delicate almond flavour ; ground into flour a very light pastry and cakes can be made from them ; roasted, they supply a kind of chocolate by no means to be despised, and boiled in alum and water they yield a beautiful sky-blue colouring matter. The carefully dried leaf is much used locally as tobacco. The seed receptacles are made into blotting-paper, and the inner part of the stalk into a fine writing paper in the manufactories of the province ; the more woody portions are consumed as fuel, and from the resulting ash much valuable potash is obtained. Experience has shown that large plantations of them in swampy places are a great protection against intermittent fever ; further, that they will grow anywhere, and in any soil with little or no attention. The best seed is obtained from the Crimea. Plants grown from this, if partially deprived of leaf and robbed of their side shoots, will furnish flowers with a least 400 seeds apiece.

TEA.

THE 1879 tea season may now be said to be wound up ; with few exceptions, the bulk of the tea has gone forward, and the outlook for dividends is not a very bright one we fear. The chief cause of this has been the low prices which the teas realised in London and here, prices which in many cases did not suffice to meet manufacturing and other charges. As we cannot now expect much improvement in these prices, with the steadily increasing production, shareholders must turn their attention to cheaper modes of manufacturing. Where labour is scarce and expensive, recourse must be had to a more extended use of machinery, and united action on the part of all concerned should be brought to bear on the Government, with a view to abolish, or materially modify those almost penal regulations regarding labour. We do not use the word "penal" in connection with the "cooly." It is applied here in regard to the treatment of the employer, who is apparently and in advance, adjudged as a particularly hard and unjust master, and crushing legislation is in consequence prepared for him. It is high time that the tea industry should be taken out of these legislative swaddling-clothes ; it being now of age, and perfectly able to take care of itself.

THE total quantity of tea exported from this to Great Britain last year was, according to Messrs. Thos. Watson & Co., 38,126,447lb., as against 33,458,071lb. exported in 1878.

INDIAN TEA FOR AUSTRALIA.

THE following important information is transmitted by Major M. Clementi, Bengal Staff Corps, Commissioner for India to the Sydney International Exhibition to the Officiating Secretary to the Government of India, Home, Revenue, and Agricultural Department :—

I have found that the firm of Messrs. Clifford, Love & Co., of 862, George-street, Sydney, are especially interested in the matter of Indian teas. During the past year they have imported into this colony of New South Wales 170 chests of tea purchased through an agent at Calcutta. They have also a tea business in connection with the colony of Queensland. They are now exhibiting a number of samples of Assam teas in the Indian court of the Sydney International Exhibition.

2. I find that the consumption of tea in this colony is at the yearly rate of ten pounds per head of the population, as against three pounds* in England. And although the population of this colony is only 700,000, yet this gives a total consumption of seven million pounds of tea per annum.

3. It is reasonable to presume that the inhabitants of the neighbouring colonies are equally large tea-consumers ; and as the total population of Australia is about one and-a-half million souls, it will be seen that the tea trade with these colonies is worth having. Beyond these, there are colonies of New Zealand and Tasmania, where the trade could be pushed with possibly profitable results.

4. The chief difficulty to overcome is the prejudice entertained by the grocers who were imposed upon some time ago by having a large consignment of very inferior Japan tea sold to them as Indian. The grocers here, too, are behind those of England in the knowledge of teas and the best trade uses to put them. In London all large grocers have mixing machines, I believe, and use them for mixing, for instance, the broken and possibly expensive ; but to the uninitiated eye inferior-looking teas, with the more handsome-looking, unbroken, but inexpensive ones, having little flavour. I am informed that there is not a single mixing machine in Sydney ; and it is, therefore, very necessary that the Indian teas thrown into this market should present a handsome appearance.

5. Messrs. Clifford, Love & Co., have a considerable business in teas with China as well as that they have with India ; and, as far as I can discover, Mr. Love is the only professional tea-taster in Sydney.

6. Mr Love assures me that with judicious management, 500 to 1,000 hests of Indian tea might be disposed of, in Sydney alone, next year, and he would undertake the disposal of them. Within seven years he feels convinced that the India teas would command the Australian markets, provided their introduction was systematically taken in hand in a business like manner.

7. At present about two million pounds of adulterated or, as it is commercially termed, "lie" tea are exported from China. This must find a market somewhere ; and as there is no law here, similar to the English one, to prevent its being imported into these colonies, no doubt but that a large quantity of it finds its way into the Australian markets, and is saleable by reason of its very low price, and because the leaf has good appearance, and liquors with a dark colour, which is mistaken for a proof of excellence of quality.

8. The Indian Pekoe Souchong is the best adapted to this market but should be fired more than it now is, that is, the tea should be a *little over* roasted so as to destroy the slightly earthy flavour common to it as it is now prepared.

9. Messrs. Clifford Love & Co., showed me their last invoices, and I find that they paid at the rate of ten annas and nine pie a pound for the tea in Calcutta, the exchange being then one shilling eight and five-eighth pence the rupee ; to this had to be added high agency charges, freight, and insurance. But I suppose that if the tea could be bought directly from the gardens, a better class of tea could be sold here to the public for the money they now asked for a more inferior sort.

10. The tea for this market should be laid down here at a cost of a shilling to one shilling and five-pence a pound, which admits of its wholesale purchase at from one shilling and eight-pence to two shillings : and then the grocers can, as they require to do here, retail it at two shillings and six-pence to three shillings the pound.

* This is wrong, the consumption in England is 4-69.—Ed., *I. A.*

JOTTINGS FROM MINCING-LANE.

THE following facts are doubtless known to many planters, but they may prove interesting to those who have not had some practical experience of the "Lane."

Brokers are divided into two branches, the selling broker and the buying broker. No less than 28 firms of brokers issued catalogues of Indian teas during the year, representing nearly half-a-million packages. There are about 12 buying brokers, who support the auctions in three ways: 1st, by buying "over" what they consider to be cheap; 2nd by executing the orders received from principals; 3rd by forcing some buyers to pay long prices. If trade is at all brisk, the leading buying brokers can buy over and place ½ per cent. brokerage fully 500 chests per day. With all their acuteness, they sometimes buy dearly, and have then to resell their purchases at a discount or give a fresh prompt. The buying brokers drop their money occasionally by dear buying, and the selling broker sometimes loses the market for his merchant by holding firmly for valuations until compelled to accept the best price he can get. It does not require the gift of prophecy to foresee however, that the time is not far distant when all Indian tea will be sold with reserve, as at the China tea sales. The course is seldom adopted just now, and there is undoubtedly some risk, but on the whole, better prices are obtained when the teas are printed for sale without reserve.

Dealers.—There are probably about 30 dealers on the London market, who do a trade of more than 5,000 chests per annum. The largest houses have from 20 to 30 agents scattered throughout the kingdom.

Warehouses.—About 14 warehouses have a share in the Indian trade, but the greatest quantity is stored by the London and St. Katherine Dock Company, whose principal warehouse is in Cutler-street, and the East and West India Dock Company. These warehouses allow 30 per cent. discount off their published tariffs, but some of the private warehouses give 40 per cent., a difference of about 6*d.* per chest. The warehouse charges are the heaviest items of the account, and sales vary from 4*s.* on chests weighing from 80 to 128lb. gross, to 4*s.* 6*d.* on chests weighing from 130 to 159lb. gross, after deducting 30 per cent. discount.

Invoices—Generally show a better result when the tea is sold by auction on arrival. If offered privately, they never receive the same amount of publicity or competition as at the public offerings. Holding teas for a better market is not a remunerative operation as the quality too often deteriorates. The probable absence of Cape shipments which used to supply our market towards the end of the season will necessitate some holding back either here or in India, and it may be mentioned that the cost of doing so here may be put down at ½*d.* per lb. per three months.

Exports.—A fair supply of Kangra Valley, Dehra Doon, and Darjeeling teas chiefly Souchongs and Pekoe Souchongs, is sent from this port to the continent, and it appears the Australian Colonies have taken this season, direct from Calcutta up to 30th October, no less than 1,300 chests. This demand may be expected to increase yearly.

Consumption.—The average *daily* deliveries for the past 6 years is as follows:—

	1874	1875	1876	1877	1878
Chests	660	860	990	1,040	1,360

but the statistics for the present year show a falling off on 1878. Various districts have their particular tastes in tea. For instance, Darjeelings are largely consumed in the north of Ireland and in Scotland, while broken Pekoes of the finest kinds are drunk pure by the lower classes in Ireland. Strong and rather burnt liquoring Assam teas are also popular in Ireland. Pale pungent teas are in great request in the midland counties of England, and in other districts, where the public taste had been accustomed to the China scented caper tea.

GREEN TEA.

IF the "deficiency" in supply be not made, it will not be for wont of efforts which the public should duly recognise. Last week upwards of 2,000 packages of green tea were sold, which were imported as long ago as 1870. The best friends of the "deal" admit that "some" of this leaf was, "no doubt, very highly coloured and objectionable" and an unprejudiced examiner describes a sample as "leaf *debris* coated with a greenish paint"—this treatment having unfortunately become necessary owing to the last having been sunk in a Thames barge some years ago. Of course, the Adulteration Act will grievously interfere with the retail of this leaf; but sellers and buyers are perfectly aware that it can be got off by judicious mixing. The public have been invited, however, to believe, that these parcels are "merely a few that still remain" of what was a few years ago "a considerable article of trade," and that these "teas" will be "chiefly shipped abroad as they are completely out of favour for the home trade." I should mention that a firm which have tasted a number of the samples, including the lot that had been soaked in the Thames, they generously say that "though a little peculiar in flavour" the same samples are quite sound and wholesome "and much less objectionable than much so called genuine tea."—*Times of India.*

THE PREPARATION OF TEA IN CHINA.

IN continuation of this subject in which the Chinese are defended to some extent against the charges of adulteration, the *Grocer* says:—We now come to the use of spent tea-leaves for the adulteration of tea. In this as well as in the other cases of alleged adulteration, the commercial evidence should be examined. Let us begin at home, and ask whether there is any such evidence to indicate that any notable proportion of the 200,000,000 pounds of tea sold in this country is largely mixed with, or as some have affirmed, entirely composed of spent tea-leaves.

Where must the spent leaves come from if such is the case? Who collects them, and where do the collectors find a market for what they have collected? It is clear that a large trade of this kind could not be carried on without making itself evident. We know that rags and bones are collected; the collectors of these are visible enough—sufficiently so to become, in some cases, a domestic nuisance. We can easily learn what becomes of kitchen stuff and candle-ends, but we fail to discover any house-to-house visitation for the collection of spent tea-leaves, or any shop-keepers to whom the cook can sell such unconsidered trifles. Neither have we been able to learn that hotel-keepers and coffee-house proprietors are able to find a market for the considerable quantities of spent tea-leaves they might save if such a market existed. It would be rash to affirm no such transactions have ever occurred, but we may safely assume that no regular business of any magnitude is carried on by means of which adulterators or sophisticators of tea could obtain supplies of raw material in the shape of spent or exhausted tea-leaves.

Eder states that out of five samples of tea bought at small shops in the suburbs of Vienna, three had been admixed with exhausted leaves. We are not able to apply the commercial test to Austria, and therefore cannot tell whether, supposing Eder's method of detecting this adulteration to be reliable, the exhausted leaves were added there or brought from China. Our limited knowledge—or rather complete ignorance—of the commercial operations of Chinese rag-and-bone men render us unable to apply the commercial test to that country; but from what is known of the very economical habits of the people, the vast quantities of tea they consume, and their aptitude in sophistication generally, it is not at all improbable that the collection of exhausted leaves may there be a regular branch, provided the labour of such collection costs less than the growing of the tea shrub and the picking of its fresh leaves. This, however, is questionable; and if some of our resident tea merchants would study this subject, they might contribute information that would be very interesting and of some practical value to the trade. Even in China an extensive traffic of this kind could not be carried on invisibly.

Eder's method of analysis for the detection of this adulteration, which he admits to be very difficult, is to first analyse a given sample of tea, then infuse a similar sample and analyse the exhausted leaves. The constituents that he determines in these analyses for this purpose are, first, the *tannin*, or that astringent principle which tea-leaves contain in common with oak, bark, catechu, divi divi, &c., and which if added to gelantine converts it into the basis of leather; secondly, the "*extract*" or mixture of peculiar gummy matters that are soluble in water; thirdly, the total ash, or all that remains when the leaves are completely burned; fourthly, that portion of this ash which is soluble in water.

The results of such comparative analyses are shown in the following table:—

PERCENTAGE.

Kind of Tea Leaf.		Original Leaves.			
		Tannin.	Extract, soluble in water.	Total ash.	Ash soluble in water.
Black Congou	... No. 1	11 20	40·30	5·43	2·83
"	... No. 2	10·10	39·40	6·21	1·55
"	... No. 3	8 36	37·60	6 05	2·32
Moning	...	11 32	39·90	5 03	3·03
Souchong	... No. 1	8 16	34·40	5 27	2·90
Assam Souchong	...	10 95	44·30	5·22	3 09
Green Hyson	...	12·44	43 20	4·89	2·77
Yellow Japan Tea	...	13 07	39 50	5·81	2·73

PERCENTAGE.

Kind of Tea Leaf.		Leaves once Infused.			
		Tannin.	Extract soluble in water.	Total Ash	Ash solube in water.
Black Congou	... No. 1	4·14	10 20	3·92	0·94
"	... No. 2	5·65	15·30	4·80	0·46
"	... No. 3	3·31	8·50	4·27	0 39
Moning	...	3 73	12 90	3 88	1·27
Souchong	... No. 1	2·51	12·40	...	...
Assam Souchong	...	5·07	19·70	4·96	1·05
Green Haysan	...	5·36	13·20	3·41	0·74
Yellow Japan Tea	...	2·62	12·00	3·40	0·47

This shows us what is taken out by the infusion, and proves that the difference between fresh and exhausted tea-leaves is very considerable. We suspect that, however, in spite of all the skill and learning of the German chemist, if several samples of fresh and exhausted tea were submitted for examination to him, and the same to an acute English laundress, the laundress would detect the difference as unerringly as the chemist. She knows well enough the difference between the first cups of tea from the pot, and those poured out after a second watering. The professional tea-taster can detect such adulteration still more efficiently, unless some very skilful disguise is perpetrated.

Is such a disguise possible? The analyses of Eder above given (and they nearly correspond with those of other chemists) afford some data for answering this question. Let us first consider the tannin. The table above shows that the percentage of this component is reduced to less than one-half by infusion. Can this be replaced so as to disguise the effect of its loss by infusion? There is no doubt that it may be. A chemist could name a multitude of vegetable substances that contain a far larger proportion of tannin than any sample of fresh tea-leaves; he could add a small quantity of these, or he can make solutions containing so much tannin, that if exhausted and dried tea-leaves were soaked in them they would take up as much tannin as they lost by their previous infusion. Logwood, oak, bark, catechu, divi divi, &c., might be used for this purpose. These would not only supply the tannin answering to the tests of the chemists, but also the rough astringent flavour and the dark colour of the infusion which the tea-drinker demands. Eder accordingly looked for such adulterants, especially for catechu and logwood. His tests for these are as follows. We state them for the benefit of our chemical readers. Non-chemists may skip them, as novel-readers skip the author's moral reflections to follow the story :—

Test for Catechu.—Make a decoction of a weighed quantity (one gramme) of good tea, and the same of the suspected sample; boil each with an excess of sugar of lead, and filter. To the filtrates (which should be colourless) add a solution of nitrate of silver. If the tea contain catechu it will produce a copious flaky precipitate of a yellow-brown colour; if not, only a slight greyish-yellow turbidity will be produced.

Test for Logwood.—Steep the tea in cold water. If logwood is present, the blackish solution which results is changed to a bright green by the addition of a little sulphuric acid. Another delicate test for logwood is the addition of a solution of yellow chromate of potash to the cold, aqueous infusion of tea; if it contain logwood, a blackish-blue colour will be produced; if the tea be pure, the chromate will have no such effect.

The next constituent—*viz.*, "extract soluble in water"—is rather a complex one. All leaves yield such an extract composed of gummy, saccharine, albuminous, and other matters, some of which are special and characteristic of the particular plant, giving it any special flavour, and any medicinal or other property it may possess. The special alkaloid the "theine," upon which the physiological properties of the tea plant mainly depends, would be here; also the special flavouring matter, such as the aromatic tea-oil, which a delicate taste detects, and which is rather disguised than otherwise by the coarser astringent flavour of the tannin. It is pretty certain that this cannot be supplied by any artificial means, and as the purity and character of this special flavour give to the better class of teas their high value, there is little risk of such teas being adulterated with exhaustive leaves by the Chinese, seeing that the adulterant would bring down the price of the sample even to a greater extent than it would increase its weight.

The coarsest and cheapest of teas contain so little of this choice flavouring extract that it is masked by the astringency of the tannin, and the drinkers of such coarse teas judge the quality mainly by this tannin flavour and the dark colour of the infusion. Therefore, we may commercially infer that the use of spent leaves as an adulterant would be limited to the coarser qualities of tea, and that some source of additional tannin would probably be added when this adulterant is used. Eder's analyses, which we shall give in our next, confirm this. The ash or mineral matter—whether soluble or insoluble—could be easily added if demanded commercially; the soluble or that which is removed by infusion, being chiefly such common salts or carbonates and oxalates of soda and potash. The following abstract of Eder's statements of the results of his full analysis of the composition of genuine teas may interest our chemical readers. Those who are not interested in such details may skip as before, and await our next, which will deal with the more commercial results :—

Average Composition of Tea.—Forty per cent. of the whole weight of the tea is soluble in water. Of this 38·3 parts are organic matters and 1·7 mineral matters. The organic matters consist of 10 per cent. of hygroscopic water; 10 per cent. of tannin; 0·2 per cent. of gallic acid, oxalic acid, and quercetin; 0·1 per cent. of bohelc acid; 2 per cent. of theine; 0·6 per cent. of tea-oil; 12 per cent. of albuminous bodies, probably legumin; and 3 to 4 per cent. of gummy substances with dextrine and sugar. The 1·7 per cent. of soluble mineral matters is composed of 0·938 of potash, 0·014 of soda, 0·036 of lime, 0·0351 of magnesia, 0·024 of sesquioxide of iron, a trace of manganese, 0·133 of phosphoric acid, a trace of sulphuric acid, 0·021 of silicic acid, 0·430 of carbonic acid, and a trace of chlorine. The remaining 60 per cent. of the tea is insoluble in water; 12·7 of this is organic matter consisting of albuminous bodies. *The etherial extractive* contains 1·8 to 2·2 per cent. of chlorophyll, 3 per cent. of resin, 1·8 per cent. of colouring matter, 16 per cent. of colouring matter, 16 per cent. of extractive matter (for the most part soluble in nitric acid), and 20 per cent. of cellulose. *The* 4·0 *per cent. of mineral matters insoluble in water* contains 0·290 per cent. of potash, 0·052 of soda, 0·515 of lime, 0·592 of magnesia, 0·045 per cent. of sesquioxide of iron, 0·019 per cent. of oxide of manganese, 1·081 per cent. of phosphoric acid, 0·046 per cent. of sulphuric acid, 0·680 of silicic acid, 0·744 of carbonic acid, and a trace of chlorine.

COFFEE.

LOCAL *versus* LONDON COFFEE SALES.

OUR morning contemporary has some forcible remarks and figures on this subject, the gist of which is as follows:—" What would be said of the merchant who always bought in the dear market, and sold in the cheap one? Who shipped produce to a foreign port in the face of a heavy loss which might be avoided by a sale on the spot? Would anyone expect him to prosper? Yet this is practically what we see done the season round, year after year. Take an instance; to-day a fair sample of plantation would very likely not be obtainable under Rs.49 f.o.b. per cwt. equivalent at 1s.8½d. exchange to 82s. 8d. sterling—or, including freight, insurance, and all London charges, equal to 93s. The present price of middling plantation is 87s., so that anyone unable to sell in Colombo, is facing a positive loss of six shillings sterling per cwt. But if it were ten shillings instead of six, most of the coffee we grow must still be shipped on planters' account, and for one reason only as far as we can see—to enable the English capitalist to make a show of doing a large business. It will be said that it is impossible to sell the whole of our coffee crop in the island, and to a certain extent this is true, but all the finer coffees would command a ready sale here were they 'f' free." The difficulty at present is to get suitable quality in sufficient quantity for direct foreign customers—and they are consequently driven to supply themselves in London where by waiting their time they are able to buy on better term than they can do here, thanks to the present plan of swamping that market with our crop as fast as it can be pushed forward through the canal by steamers. We could name a large number of crops, which, if sold in the island, would realize much better prices than they do at home. There is, however, no help for it; they *must* be shipped—that is in the bond from which there is no appeal. Some years ago, extensive orders used to be recieved from France, Belgium, Russia, and the United States, but of late the direct trade with these countries has dwindled down to the most insignificant proportions. A strange fact apparently, when we consider the extension of cheap steam communication since the opening of the Canal, but in no way surprising if we look at the cause. Taking the price of plantation to be Rs. 49 f. o. b., and exchange at 1s. 8d. the sterling, the equivalent is 81s. 9d. to which must be added, say 11s. for freight, insurance, and usual home charges, thus making the cost 92s. 9d. and showing a loss of 5s. 9d. per cwt. on a quotation of 87s. It is therfore clear that if a Frenchman is willing to pay the equivalent of 81s. 9d. sterling to the seller direct, in Colombo, the latter will realize 5s. 9d. per cwt. more than he could expect to do in London. But this is not all. The foreigner if buying there at 87s., would have to add say 3s. to this price for expenses of transport and other charges, so that actually he is saying 90s. for an article which, if it had been bought on the spot, would have left the grower 83s. 6d. net sterling against 76s. net sterling from a sale in London. A difference of 7s. 6d., or less (say 2s. 6d. the merchant's selling commission), of 5s. net gain by a sale in the island. This will be seen more clearly from the following calculation :—

	s.	d.
London price	87	0
Freight and transport from London	3	0
Actual cost at Wharf in Marseilles	90	0
Deduct freight and charges from Colombo to Marseilles ...	6	6
Leaving	83	6

as the net sterling price that could be paid in Colombo for an order on French account. In this instance, we have taken the Marseilles market, but the same facts apply equally to other continental ports. If coffee proprietors here be in a position to have their interests sacrificed in this way to the whims of home firms, well and good, but if they are not, then it might be as well, whilst seeking to economise in estate management, if they wer at the same time to seek relief as far as possible from a cruel incubus, which is becoming a more intolerable burden every day."

We do not suppose their is anything new in all this to our planting community. It has been a well-known fact for some years back, more especially since the advent in our midst of the representatives of German and French coffee-buying houses and the establishment of a coffee market in Colombo, that it is more advantageous for the planter as a rule to sell locally than to ship to London. We suppose very few independent planters, at liberty to sell or ship as they choose, have adopted the latter alternative for some years back. The cause of so large a proportion of our produce being shipped to

London is familiar to us all, and it seems particularly cruel of our contemporary, at the very time when a large number of our planters are realizing more keenly than ever their dependence on English capital to turn round and say "Why don't you sell your produce in the local market—why ship your coffee to London." He might as well ask, "why go and borrow money at ten per cent. from a mercantile firm here or at seven per cent. from a London house; why not employ local brokers to get the money for you?" Was there ever a more unseasonable moment to go and open the old sore of local *versus* London coffee sales than at present, when so many of our planters are pressing both Colombo and London houses to take up their accounts—when money to carry on with is scarcely to be had on almost any reasonable terms, and when it is of particular importance to try and induce English merchants to increase their investment of capital in the business of this island? This is how it strikes us while fully alive to the hardship imposed on the producer by the present mercantile stipulation that coffee must be shipped and sold at home. It is simply the old old story:—"The rich ruleth over the poor and the borrower is servant to the lender." If the London merchant advances his money only on condition that it brings him besides the stated amount of interest, so much business in the shape of produce to sell in Mincing-lane, who is to say him 'Nay'—at any rate at the present moment? He cannot and does not force his money on the producer. The latter is quit at liberty if he care to get his capital independently, and if he so manages, to sell when and where he please. But until this financial crisis has passed away, we cannot help suspecting that the number of grumblers against the system which binds them to ship, will not be so great as the number who are anxious to get accounts taken up and the wherewithal to carry on even if they have to ship every bean at the disadvantage our contemporary points out. It may be asked, however, if our German and French local houses are so anxious to obtain fine plantation coffee for direct shipment to the Continent, so undoubtedly saving extra freight, charges and commission, why do they not enter into advance business—why not invest some of their capital in helping the producers at this crisis to carry on—why not take a little of the risk appertaining to estate accounts? From the point of view of the London merchants and their Colombo agents, the remarks of our contemporary will, in fact, appear eminently one-sided and unfair. Their answer will be:—"You want us no doubt to continue the investment of our capital in the accounts on our books, but to allow our constituents to sell their coffee to French and German rival mercantile houses on the spot, in order that the planter and the purchaser may divide a profit which now comes to us and our supporters as part of the return we reckon on against the risk of occasional bad accounts and heavy losses." It may seem somewhat strange for the *Observer* to be thus standing up for London capitalists and agency houses in a business practice undoubtedly prejudicial to the producers; but we cannot help remembering that at this moment the most urgent requirement of the producers is an additional supply of money which only the said capitalists appear to be able to afford. What at this time, would be the value of liberty to sell crops in the local market if the wherewithal to weed the plantation, to buy rice and gather in the crop is withheld? Is it not a fact that some of our planters would be right glad to get their accounts taken up on condition of shipping produce to London; while there are others who for weeks and months have been waiting in the hope of advances on any more independent terms. So scarce is money that we have heard of cases of men with clean title-deeds (for young properties) being unable to raise a moderate loan on primary mortgage (at good interest, but without other conditions), to carry on. At such a time then, we fear that while to the independent planter the news will be trite enough of the advantages of selling his coffee locally rather than in London, to the rest of the planting community the convincing figures adduced to show how 6*s*. a cwt. may be saved, will seem like a mockery of them and their dependence. If continental buyers really desire to promote direct sales and shipments, they ought certainly through their own locally experienced agents to make advances against crops, to undertake business somewhat similar to that of the "Cash Credit System," which carefully managed ought to be free of any special risk.—*Ceylon Observer.*

COFFEE TWO CENTURIES AGO.

IN the book entitled "Isagoge Phytologica," published in 1690, to which we recently made reference, the following appears relative to coffee:—

"COFFEE—*Cophy.*—It groweth on little trees, only in the deserts of Arabia. The time is not observed. As for the variety of names, authors have as yet writ little. Coffee is of an exsiccant quality. It dryeth up the crudities of the stomach, comforteth the braine, it benefits consumptions, lethargies, rickets, swounings of women, it fortifyeth the sight with its steem, and prevents dropsies, gouts, and the scurvie, together with the spleen and hypocondriacall winds; all of which it doth without distemper. Hereof may be made an eletuary, thus. Take of butter and sallet oile equal parts, mixed, and melt them with thrice so much hony and Turkish coffee, a sufficient quantity of rumsey; the quantity (the size of) a nutmeg taken, opens the body, and helpeth the stone and gout. The *grains* and *berries* called coffee are brought from Arabia, and drunk generally throughout all the Grand Seigniour's dominions, and about halfe a pint is to be drunk fasting, an houre before, and not eating an houre after, as hot as may be endured, it not fetching the skin of the mouth, or raising blisters by its heat. The Turks drink it to help their crudities, drinking water and eating much fruit, which cause it. This drink is cold and dry, and when hot or in flames more than hot posset. It closeth the mouth of the stomach and helps digestion, and so may be taken at 3 of the clock in the afternoon or 4, as well as in the morning. It much quickens the spirits, and makes the heart lightsome; the steem helpeth sore eyes; its good against a cough and cold; suppresseth fumes, and so helpeth the headache; stops defluxions, and prevents the cough of the lungs. It's better than any other drying drinks for old people, and children having running humours as the king's evill, &c. It prevents abortion and drousiness, hindring sleep for 3 or 4 houres, taken after supper. It helps the stone, whitens the skin, and is not laxative or binding.

CINCHONA.

THE Superintendent of an estate in Dimbula sent the proprietor a specimen with the following note:—"Enclosed is a bit of renewed cinchona bark with roots growing out of it. I was looking at a tree to see how the bark was renewing and on taking the moss off found these roots growing out of the new bark. Rather curious is it not, for it was some 5 or 6 feet above the ground." The specimen and note were referred to Dr. Thwaites, who wrote:—"With reference to your's of the 27th, enclosing a specimen from a cinchona stem with young roots being developed, this phenomenon has arisen from the bark having been cut too deep and into the true wood, when of course roots are produced under a covering of damp moss; under similar circumstances we get what are called Chinese grafts for propagation of many of our trees, such as mangoes, oranges, &c."

THE MADRAS CINCHONA PLANTATIONS.

THE following order of Government has been issued on the report of the Commissioner of the Neilgherries:—

"The report of the Commissioner shows that satisfactory efforts, were made to maintain the condition of the Government Cinchona Plantations during the year 1878-79. The seasons were favorable to the growth of the trees, but the rainfall was too limited and infrequent to allow of the bark "rising" freely and continuously. Labor was still scarce at Neddivattum and Pykara, but out of the allotment of Rs. 24,125 for the general up-keep and conservancy of the plantation, Rs. 23,530 were utilized. Manuring was also carried out more extensively than usual, except at Pykara where there is always a difficulty in procuring manure. This defect demands prompt attention and the Commissioner's promised proposals on the matter should be submitted at a very early date. The yield of the year was 114,320 of dry bark, and the Commissioner has appended to his report a statement of the plot, and number of trees in each, from which bark was taken. The trees it appears are barked, not by plots but according to their growth and individual capacity to yield. Under the "mossing" system of barking, therefore, the yield is necessarily calculated per tree, and the results for each plantation are shown in the following abstract statement prepared from that above referred to, and the figures given in paragraph 6 of the report:—

Trees Barked.		Weight of Bark.		Average Yield per Tree.	
Kind.	Number.	Wet.	Dry.	Wet.	Dry.
		lb.	lb.	lb. oz.	lb. oz.
Crown* ...	33,331	65,755	27,062	1 15	0 12
Crown† ...	28,056	53,948	26,602	1 10	0 15
Red† ...	17,715	93,690	43,[illegible]43	4 6	2 7
Crown‡ ...	18,985	30,549	5 475	1 9	0 4
Red‡ ...	12,799	38,399	11,888	3 0	0 14
Total ...	1,10,869	2,82,341	1,14,120	2 8	1 0

*Dodabetta Plantation. †Neddivattum, Plantation. ‡Pykara Plantation.

These results are very satisfactory, especially for the Neddivattum and Dodabetta Plantations. Dr. Bidie, in the notes on the Pykara Plantations which he visited while this crop was being taken, remarked that the bark would be very light when dried, and his prediction is fully borne out by the figures given above, which make it evident that very careful treatment and cultivation are imperatively demanded to maintain the trees on this plantation. From the year's crop dry bark, 108,514lb. were sent to England, and being there sold at prices which showed an advance on those of the previous year—realised £26,159:

but as only a portion was sold before the end of the year, this amount doesnot appear in its assets. The receipts of the year as returned by the Commissioner, Rs. 406.217-85, are made up of the sum obtained in England for the bark of 1877-78, and the value of so much of the 1878-79 crop as was supplied to departments, &c., in this country *plus* gain by exchange at 1*s.* 9*d.* the rupee. It is presumed that in adopting this rate, the Commissioner, as directed in the order, ascertained that it was fixed for the adjustment of transactions between England and India in the year under report. The valuation of the bark departmentally supplied seems fair, but the Government do not consider that credit should be taken for the gain by exchange that would have accrued if the bark had been sold in England, as, though a debit allowance for carriage and freight is made, the broker's charges and other expenses incidental to the English sales cannot be accurately estimated. Moreover no credit should be taken for the bark that was the subject of the experiments recorded in G. O., 9th May 1879; No 1022, as it has been sent to England for sale and the proceeds will appear in the receipts of the present year. After these deductions are made, the receipts of 1878-79 will stand at Rs. 400,854-33. The public demand for seed and plants was abnormally large, but appears to have been fully met. The sales of 1877-78, *viz.*, plants 187,850, seeds 326 lb. were in excess anything previously known, but were far below those of 1878-79 :—

Plants	604,855
Seeds	1,822 lb.

showing the rapid progress recently made in Cinchona cultivation in this Presidency and Ceylon: The Government regret to learn that so large a number of the young plants raised at Neddivattum from the *Calisayo Ledgeriana* seed received from Java have died. The larger measure of success obtained at Dodabetta would indicate that the nurture of this delicate variety is there better understood or is conducted under more favourable conditions. It would be well therefore that a larger proportion of any further supply of this seed should be shown in its propagating houses. The second parcel of seed which has only recently arrived, contains a far smaller consignment than that which was stated to be required for Government purposes and distribution in the Wynaad, and under these circumstances it is not understood why a portion of it has been sent to planters in Travancore. The erection of new drying houses must await the report from England as to the comparative chemical and commercial value of the samples of bark sent home under G. O., 9th May, 1879, No. 1022."

SILK.

IN consequence of the general failure of the silk trade, there are at present in Calcutta a number of continental gentlemen, who have especially come to India to inquire into the silk produce of the country. One of these, Signor Papayanni, has, in the course of his travels fallen upon a district on the confines of Burmah and China, the inhabitants of which are in the habit of using the worm *Bombyx attacus yarna mahi*, as food, when it is about to spin, or technically speaking when it is in its sixth stage. He states that the people regard it as a great delicacy. The chrysalis also is used as an article of food, being previously stripped of the cocoon, which is thrown away. The explorer, Signor Papayanni, we are informed, sent to Marseilles, in November last, a box containing a quantity of these cast off cocoons, which he picked up on the road side, and which realised the handsome sum of Rs. 300. This enterprising gentleman, we learn, will shortly make a second trip.

SILKWORM "CROSSING."

AT the International Congress of Geography, at Brussels, Mr. Rogers, late Bombay Civil Service, called attention to a communication made by him last year at the Paris Congress respecting the indigenous Indian worm that spins the Tusser silk, a product resembling that spun by the Japanese oak silkworm *Yama. Mai.* The Indian worm can be advantageously crossed with that of Japan, and the crossed breed, not being dependent exclusively on the mulberry tree for food will flourish on the leaves of common trees, especially those of the fig tribe. Silk, the produce of the indigenous worm, can be produced in any quantity in India, and a further recommendation of the species is its hardiness. It is also said to be probably free from the maladies to which worms that feed on the mulberry tree are subject.

DEVELOPMENT OF SILK INDUSTRY.

(*Abridged from the 'Mainichi Shimbun.'*)

WE have consistently advocated the establishment of fresh industrial undertakings. We consider that it is only by increasing the wealth and importance of the country that we shall advance in the scale of civilization and obtain all the rights and privileges of an independent nation and the only way to accomplish these objects is to encourage and foster those industrial undertakings which lay the foundations of a prosperous commerce.

Although many writers on the subject agree generally with our views, yet there are some who are very anxious to see Japan develop her resources immediately and therefore advocate the introduction of foreign capital, while others again, considering that the attempt to make Japan a great manufacturing country must inevitably prove successful, actually suggest the reduction of the price of produce and a consequent diminution in the specie of the nation. If either of these recommendations are adopted how can the wealth of the country be increased ? No doubt industries cannot be easily made successful in the face of the rivalry which exists, nor can a nation acquire great wealth and power in a day, but those who feel despondent should reflect upon the past state of many countries in Europe, and compare it with the prosperity they now enjoy. These countries were not always so wealthy and powerful as at present, indeed, not so very many years since, some of them were in a more backward state than we are. Under these circumstances we should not despair of achieving the same success in the course of time.

Many people allege that the industrial resources of Japan are not developing, and yet we find on examination, that numerous industries have been established since 1877. Prominent amongst these are the silk-reeling establishment at Tomioka, the *Shindzuisha* (match factory) of Tokio, the ship-building yards of Messrs. Kawasaki, Hirano, Shiramino, and tens of others, the cotton mills of Sakai, Hiroshima, and Kanasawa, the black tea factories in Kishiwada, Matsuyma, and many other industries, all of which have been but lately established.

Far beyond all others has been a remarkable increase in the development of the silk trade, and we will here furnish our readers with a list of the different filatures, the localities where they are situated, the number of work-people employed in each, and the annual production of the different establishments. (*Here follows the table.*)

It will be seen that this industry has been commenced in 27 different prefectures and that 702 filatures have been established, employing no less that 11,135 work people. About one or two per cent. of these filatures have closed for the present or are not yet finally completed, and although the first started began operations in 1865, and the latest this year; the majority were established in 1876-7-8. The motive power in these factories is supplied by steam, water-power, and manual labour, eighty or ninety per cent. of the filatures being worked by water-power and only three by steam.

Our readers will now perceive that industrial undertakings are steadily increasing year by year in this country. Silk being the principal product of Japan, it is only natural that this particular branch should experience the most rapid development, but even then it is remarkable to find no less than over 700 different filatures established in a very little over ten years, the vast majority being within the last three or four years. Silk affords the best example of what may be done in other branches of business and who, in the face of the examples we have quoted, can assert that industrial undertakings will not flourish in Japan ?

We trust that our countrymen will ponder over what we have brought forward and strive to increase the national wealth and power by the establishment of industries, and thus in course time, bring Japan on a level with the countries of Europe and America.

TOBACCO.

WE understand that Mr. J. H. V. Cureswell, late of the Government tobacco farm, has entered into an engagement with an extensive land-owner and planter of Rohilkhund and Tirhoot, with a view to opening a plantation for the cultivation and manufacture of tobacco. Mr. Cureswell has lately been curing tobacco in Calcutta.

TOBACCO IN ARAKAN.

WE have been favoured with the following reports from Major Hughes, which are sufficiently interesting in themselves, and do not require any notice from us. At the same time we may be permitted to congratulate the authorities concerned, in the success of their efforts to push on this great industry, for it only requires a little more development to make it a great industry. This tobacco was worth say 4½*d.* per lb. in London, that is to say Rs. 15 per maund, or, at the present exchange of 1-8⅜*d.* to Rs. 16-8 per maund. As this was the first consignment, the result must be considered very satisfactory, as the curer will by a little more experience get over the difficulties appertaining to climate, which have always stood in the way, but which can doubtless be reduced to a minimum by care and skill. This should open up a new industry almost, and if thoroughly successful, will have the advantages over tea and coffee of speedy returns. There is an almost unlimited demand for the article, and as no difficulties exist on the growing; we are pleased to see that the curing difficulty is being grappled with successfully.*

* The reports will be found among other official papers in another column.—Ed., *I. A.*

A GOOD deal of useful information is contained in Mr. Buck's report on tobacco operations in the N.-W. Provinces for 1878-79. As might have been expected from the practical bent of Mr. Buck's mind, we find that attention was given largely to the curing, which has hitherto been the weak point in all our experiments. Five practical curers were at work, and four methods were tried to find which suited best the Indian grown leaf and the Indian climate. The four systems tried were drying by sun heat, air, wood-fire, and flue heat, the latter having been found to give the best results. Outside furnaces with internal flues have been constructed at the factories. On hot clear days sun-drying was found very effective, but it has its drawbacks, the exposure to the air during the hot months making the tobacco liable to get spoiled from dust, and during the rains, when there is no dust, the periods of sunshine are intermittent, and this interferes with the continuous process.

The quantity cured was 1,650lb., and the machinery now at work, while turning out 500lb. a day, is capable of manufacturing 3,500lb. daily. The prices obtained in the London market, for the crop of 1876-77, were such as to warrant the conclusion that the experiment should become financially successful. Some of it sold as high as 7*d.* per lb., while the greater part sold from 5*d.* and over, and this was when the market was acknowledged to be about 25 per cent. below *par* as regards prices. The price at the same time of the corresponding qualities from America ranged from 5*d.* to 6*d.*, while the higher bright leaf from Virginia realised from 7*d.* to 13*d.* per lb.—a success towards which our curers are no doubt working. Cigar-making has not been tried, all efforts having been concentrated on manufacturing cake and smoking mixture, and the success which has attended this is shown by the sales, which now average 1,000lb. per month and are steadily increasing; and orders are now coming in from Australia and New Zealand, which is a hopeful feature in connection with the industry. The manufacture of smoking tobacco, either in the form of cake or mixture, has another advantage over cigar-making, in that it uses up scraps, which, although quite as good as whole leaf, are unsaleable in the home market. We should not need to fear competition with America, as our cheaper labour enables us to grow and cultivate the article more cheaply than can be done in the United States.

A selling price of 4½*d.* per lb. in England will make the venture a commercial success, and a higher average rate than this has been obtained already, so that with the experience gained from the earlier working, success from a financial point of view may be assumed. Every penny per pound obtained over 4½*d.*, will give a profit of Rs. 50 per acre. The Government has leased the farms and factories to a commercial firm, who have better opportunities of getting sale for the produce, and Mr. Buck tells us that the Government will continue to render such assistance in the prosecution of the undertaking as they might reasonably be expected to give.

INDIAN TOBACCO.

THE time seems to be approaching when Indian tobacco will really be placed in competition with American. The progress in the North-West last year was very encouraging, and as an official report just issued shows the enterprise is now conducted on a rather extensive scale. Five Europeans, or Americans, were engaged on the operations connected with experiments at Ghazipur and Pusa; the area cultivated being 239 acres, and the estimated outturn of cured leaf 165,000lb. During the latter portion of the year natives were instructed in the various and complicated details for manufacturing, and at the present time every class of manufactured tobacco is being turned out. It is said that there is no kind of tobacco, smoking mixture or cake, which cannot be manufactured of a quality equal to that of the same class of American, while for this country the Indian brands are likely to prove superior to the American, since it is well-known that America does not ship her best qualities to the Indian market. Orders have come from Australia, and arrangements have been made to send consignments to New Zealand of the manufactured smoking tobaccos; while a new market is not unlikely to open in France, for the French Government have already asked for and received samples, which they have pronounced to be better than any they have had from India before, and they have shown their practical appreciation of its quality by asking for a larger consignment for trial, to the extent of 1,000 or 1,500lb. No mention has yet been made of cigars, but these, it is suggested, will come in time, now that the more serious attempt to meet the most important composition in the field has been made. The machinery at Ghazipur is capable of turning out 3,500lb. a day as soon as a sufficient number of hands have been probably trained; and when it is understood that it takes twelve months to train a factory hand in America, the progress which is being made must be considered highly satisfactory.—*Times of India.*

THE POSITION OF TOBACCO CULTURE IN INDIA.

SORTING.—Tobacco intended for smoking should be carefully sorted when stripped. There should be four sorts, *viz.*, 1st, large, equally good coloured untorn leaves; 2nd, leaves of good size and colour but torn; 3rd, leaves of inferior colour and bottom leaves; and 4th, the refuse containing shrivelled up leaves, &c., to which may be added the suckers. Leaves under No. 1 when thin, elastic and of good species are mostly valued as wrappers (outside covers) for cigars. No. 2 may also be used as wrappers but are less valued than No. 1; they are adapted for fillers and cut tobacco. The different sorts should be kept separate. The best plan is to let the most intelligent man strip the leaves from the stem and at once separate them according to quality. The leaves should then be made into hands, that is 10 to 20 leaves should be tied together by twisting a leaf round the end of the stalks; each sort should be attended by a special man to avoid mixing. The leaves of the first sort being large, 10 to 15 leaves will be sufficient for a hand. To make up a hand more leaves are required from the other sorts. When making the hands of the two first sorts, the man should take each leaf separately, smooth the same on a flat board, leave it there and take another leaf treating it in the same way, and continue thus until a sufficient number is ready to make a hand. When the hand is ready it should be laid aside, and a weight placed upon it to keep the leaves smooth.

Bulking.—Bulking means placing the tobacco leaves in heaps, for the purpose of heating it, in order to attain colour and flavour; this is carried out in various ways, nearly all of which involving great labour and risk, as in most instances tobacco loses more or less in value during the process called curing. It must here be mentioned that the more care is taken in raising the crop, the less attention the tobacco requires in the shed. With a good species of tobacco grown on light friable soil, treated as laid down in this paper, and the leaves dried as mentioned above, little care will be needed, after the leaves are dried and stripped. By the drying process described the leaves will have undergone a slow fermentation, which makes it unnecessary to watch or guide a regular fermentation afterwards, hence bulking and fermenting as generally understood are not required.

The tobacco after being made into hands should be put into heaps (bulked) before it again dries. Every evening the tobacco that has been stripped during the day should be bulked, but if the weather be very dry the tobacco must be bulked as soon as a certain number of hands is ready. The heaps should be made from 4 to 8 feet square and from 4 to 8 feet high; all the stalks should be outside, and the whole covered by mats, &c., to check evaporation. The drier the tobacco, the larger must the heaps be made to encourage a slight fermentation. The extent of the fermentation can be easily controlled. If the colour of the leaves is not uniform, or if it is desired to give them a browner colour then the heaps must be made large, and a somewhat moist atmosphere is required in the storing-room. This will cause fermentation to set in after a short time, and the heat to rise after some days so much that rebulking is required, which is done by putting the top leaves of the old heap at the bottom of the new one. Under such circumstances the heap must be frequently examined during the first few weeks to prevent overheating. It is advisable to rebulk the tobacco also, even when not much heated after the first fourteen days, and again a month later to ascertain the exact state in which it is. Sometimes the tobacco becomes mouldy; this may occur especially with tobacco which has been manured with chlorides, which cause the tobacco to become more hygroscopic than when manured otherwise. If this occur, the mould must be brushed off, and, if necessary, the tobacco dried. The tobacco may now remain heaped in the store-room until there is a chance for sale. It must be remembered, however, that the best time for sale varies very much. Some tobacco is fit for smoking a few weeks after drying, whereas others burn very badly at that time, but nevertheless sometimes become a good burning article after being stored for several months.

It is sometimes the custom to subject the tobacco leaves to some sort of improvement. There is no doubt that by proper application of ingredient the value of tobacco may be much enhanced. The most costly tobacco often commands a high price not so much on account of its inherent flavour as on account of that given to it artificially. In most instances the best course to be adopted is to leave the improvement of the leaves to the manufactures. Many ingredients are employed to improve smoking tobacco. They tend—

1. To make the tobacco more elastic and flexible.
2. To remove the coarse flavour.
3. To add a particular flavour.
4. To improve the burning quality.
5. To improve the colour.

To make the tobacco more flexible and pliant the leaves are macerated in or sprinkled with, a solution of sugar. In hot countries this is often necessary to give tobacco such an elasticity as to become fit for handling, especially when intended, for wrappers, and may be done by an intelligent cultivator.

To remove the coarse flavour, tobacco is often macerated in water or in a solution of hydrochloric acid. To 100lb. of tobacco 4 to 8 ounces of hydrochloric acid diluted with 25 to 30 measures of water is applied in Holland; the more coarse the flavour of the tobacco, the stronger is the solution used. The time of maceration varies between half-an-hour and an hour. Sometimes tobacco is steeped in a mixture of sugar solution and

diluted hydrochloric acid. To extract the fatty matter tobacco is macerated in alcohol or spirit of wine.

To give tobacco a fine flavour numerous substances are employed, some of which are kept secret. In the maceration of tobacco for the purpose of influencing the flavour, the following ingredients are mostly in use :—water muscatlee, cognac, vanille, sugar, rose-wood, nelc-wood, cassia, clove, benzoin, citoro oil, rose-wood oil, amber thyme, lavender, raisins, sassafras wood, saltpetre, orange, and many others. The burning quality is improved by macerating tobacco in or sprinkling it with a solution of carbonate of potash, acetate of potash, acetate of lime, saltpetre, &c. Badly burning cigars inserted for a moment in such solutions are much improved. Tobacco treated with acetate of lime yielded a very white ash.

The colour of tobacco is sometimes improved by fumigating the leaves with sulphur and by the application of ochre and curcuma.

Although it may be said that fine tobaccos generally do not require any impregnation with foreign matter for the sake of flavour, yet the manufacturer resorts frequently to it to give the leaf a particular aroma. An inferior tobacco, however, which often would not find a market is so much improved by artificial means as to compete successfully with the genuine fine article.* A special preparation of tobacco for snuff is seldom attempted by the cultivator. With reference to the preparation of tobacco for export, the sorting of the leaf is of the utmost importance. Only first and second sorts should be exported. It would be well to remove the mid-ribs, whereby the cost of transport and customs duty would be greatly reduced.

Finally, it must be mentioned that the value of a cigar depends not only on the intrinsic value of the leaf, but to a great extent on the mode of manufacturing the article. Thus the raw material may be of good quality, but if the maker does not classify the leaves properly, or if he rolls his cigars too hard, which must vary according to the qualities of the leaves, the cigar will burn badly. The best burning leaves must always be used for wrappers. If this should be neglected the inside of the cigar burns faster than the covering, the air has no access to the burning parts, and the empyreumatical substances are volatilized without being decomposed. Such cigars therefore make much smoke and smell badly.—*K. Schiffmayer, Asst. Supt., Government Farms.*

* It is said that in Germany, indigenous tobacco is often so much improved that the cigars made from it after being covered with a fine tobacco leaf are sold as genuine Havanas.

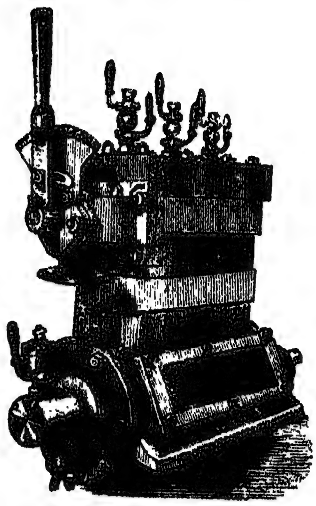
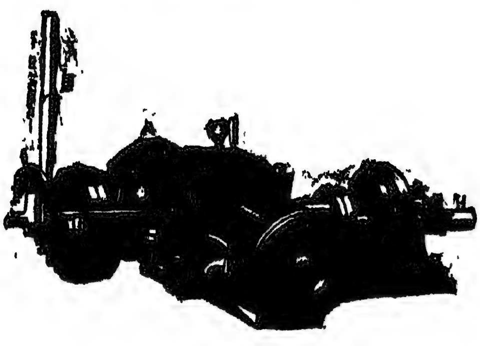
Price, Rs. 4,250. Of Steel throughout.

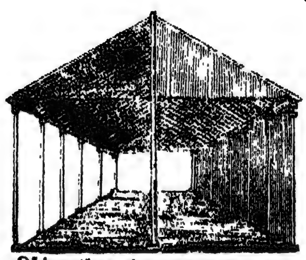
33 ft. long draught 18 in. speed, 14 miles per hour.



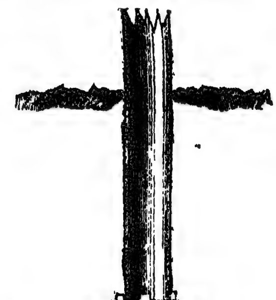
Shews Patent 3 Cylr. Compound and High Pressure, Expansive Engine fitted to Canoes, Gigs, & Launches.



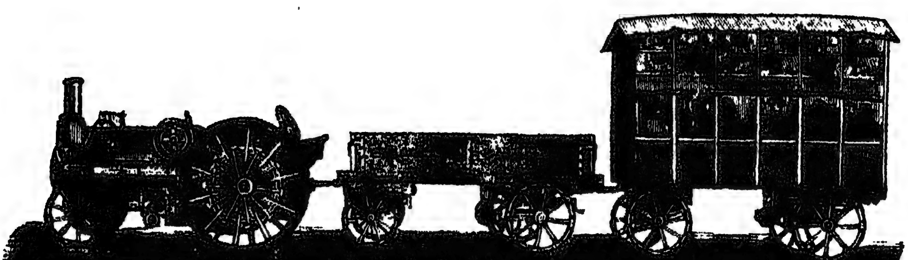
Patent Stationary 2 Cylr. Engine from 2½ to 33 H.P.



Of iron throughout. No tie-rods whatever, easily erected by coolies.



Shews Pillar and Foot Plate, for shed obviating use of Masonry.



Road Locomotive with goods truck and Passenger Carriage for use on *kutcha* Mofussil roads, and designed for European enterprise against the Bullock-cart traffic, Price, Rs. 4,500.

The Canoes and Gigs are built for the roughest waters, large rivers, creeks, or jheels, doing all the work of a large launch; coal Re. 1 per diem. The Engines are stopped or reversed solely by one lever from full power ahead to full power astern. The boilers are made to work in fresh or salt water with any class of fuel, most uninitiated can work them; especially designed for Tea and other Planters, Traders, Zemindars, and others, when not in use easily lifted into a verandah and cannot warp. Folding Boats are of best material and workmanship patented in Calcutta, 1875 and 1879, can be folded up or opened out in a minute. None heretofore built worthy the name since a 10ft. Boat folded up, measures 10ft., and costs Rs. 160 to 210. The sheds are designed for. Planters, Traders, Contractors, and others, any body can put them up, price of one covering area of 784 sq. ft. to hold 1,000 drums of jute, Rs. 1,600 Patents, 2 Cylr. Stationary or Portable Engines on Wheels for Bullock draught 2½ H. P., Rs. 1,350, 5 H. P.. Rs. 2,250. Most economical in fuel, the working controlled solely by 1 lever and requiring no skilled driver. All sorts of trading and agricultural requirements patent seed-sifting machines without wheels, cracks, or other complications specially constructed for Mofussil country produce traders capable of being worked by 2 Boonooa coolies and turning out 150 mds., price Rs. 110, Galvanized Fencing Wire at greatly reduced prices, Patent Wheel Hoes for hoeing between rows of crops. Patented process and apparatus for Manufacturing sugar from date juice.

ADDRESS, E. WARD & CO.,

KISSENGUNGE, NUDDEA, BENGAL.

SEVEN PRIZE MEDALS awarded to GOODALL'S HOUSEHOLD SPECIALITIES. A single trial solicited from those who have not yet tried these preparations.

Goodall's Yorkshire Relish

THE most delicious sauce in the world; enriches hot joints, stews, chops, fish, &c.; with soup it is charming, blends admirably with all gravies; makes cold meat a luxury; makes the plainest viands palatable; the daintiest dishes more delicious; a great addition to cheese; every dish is improved by its addition; epicures pronounce it the best sauce; beware of colourable imitations.

CAUTION.—It having come to our knowledge that an imitation of our celebrated Sauce, the Yorkshire Relish, is being palmed upon purchasers, we beg that they will insist upon having the only genuine Yorkshire Relish, bearing a label with the Trade Mark, a "Willow Pattern Plate," and our name, "GOODALL, BACKHOUSE and Co., LEEDS," with a protecting label over the stopper. We are sorry that respectable tradesmen should lend themselves to such an imposture for the sake of a little extra profit. Sold by Grocers, Oilmen, Chemists, &c., in bottles, 6d., 1s., and 2s. each.

Goodall's Baking Powder

AWARDED Seven Prize Medals for superior quality. The best in the world. Defies comparison. Makes delicious puddings without eggs, pastry without butter, and beautiful light bread without yeast. One trial will convince the most sceptical of its superiority over others.

Sold by Grocers, Oilmen and Chemists, &c., in 1d. packets, 6d., 1s., 2s., and 5s. tins.

Goodall's Custard Powder

FOR making delicious custards without eggs, in less time and at half the price. Delicious to plum pudding and jam tarts; delicious to stewed rice and all kinds of fruit; delicious to everything; delicious alone.

Give it a trial.—Sold in boxes, 6d. and 1s. each, by Grocers, Chemists, Italian Warehousemen, &c.

Goodall's Egg Powder

ACKNOWLEDGED to be the only real substitute for eggs yet discovered; its action on Cakes, Puddings, &c., &c., resembles that of the egg in every particular, enriching them in colour and flavour, rendering them most wholesome and nutritious. One penny packet will go as far as four eggs! and one sixpenny tin as far as twenty-eight!

Sold everywhere, in 1d. Packets; 6d. and 1s. Tins.

Goodall's Ginger Beer Powder

MAKES three gallons of the best Ginger Beer in the world for threepence. Invaluable for producing a delicious and invigorating beverage, possessing valuable medicinal properties, thereby rendering it the most wholesome and perfect beverage ever discovered for both winter and summer use, is easily made, and acknowledged the best and cheapest.

Sold in packets, 3d. and 6d. each, by all Grocers, Chemists, and Italian Warehousemen, &c.

Goodall's Quinine Wine

IS invaluable for indigestion nervousness, gout, rheumatics, &c. A wineglassful twice or thrice a day will be found both grateful and efficacious in all cases in which a cordial tonic is required, far superior to sherry and bitters or bitter beer.

Sold by Chemists, Grocers, &c., at 2s. per bottle.

Goodall's Mushroom Ketchup

CONFIDENTLY recommended to all true lovers of the Pure Mushroom. Prepared by a special Steam process, from the PURE JUICE, producing a FULL AND RICH FLAVOURED KETCHUP, unrivalled for its GREAT STRENGTH! PERFECT PURITY!! and UNSURPASSED FLAVOUR!!!

Sold in bottles at 6d., 1s., and 2s. each, by Grocers, Oilmen, and Italian Warehousemen all over the kingdom.

Goodall's Brunswick Black

FOR Painting Stoves, Grates, Iron, Tin, &c. This invaluable composition is superior to any yet offered to the public, possessing great brilliancy and thoroughly protecting the articles it is applied to.

Sold in bottles at 6d. and 1s. each by Grocers, Oilmen, Chemists, Italian Warehousemen, Ship Store Dealers, &c. Shippers and the Trade supplied by the Sole Proprietors,

GOODALL, BACKHOUSE, & CO., White Horse Street, Leeds, ENGLAND.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

CORRESPONDENCE.

TEA DRYING MACHINES.

TO THE EDITOR.

SIR,—The assertion made in a home (English) paper by an expert to which attention was drawn in the *Englishman* of the 6th instant, to the effect that Indian teas rapidly deteriorate in flavour and will not keep, is supported by continental opinion, a similar assertion having been made some ten months ago in the *Journal der Physik und Chemie.* The majority of scientists who have investgated the subject agree that placed under similar influences, Indian tea will lose flavour and decompose more rapidly than Chinese teas. Whether this is due to insufficient drying or to the use of machinery in the rolling process, is an important question to solve for those most interested.

What I desire to draw attention to, is that the tea industry of India runs, in my opinion, a great danger of increasing this defect. The danger I refer to, is the yearly increasing quantity of tea dried by heated air. Charcoal, it may be well to remind tea planters, is not pure carbon, but retains always some volatile ingredients, possessing important antiseptic qualities.

Tea dried by direct contact with the fumes and products of combustion of charcoal, will, it may therefore be fairly assumed, less easily deteriorate than that dried by heated air not containing any antiseptic qualities. As I believe most patentees of tea drying machines to be sincerely interested in the true development of this industry, I do not hesitate to recommend them to obtain evidence that the danger above referred to does not exist.

EUGENE C. SCHROTTKY.

Calcutta, February 10th, 1880.

CASCARILLA AND CINCHONA BARKS.

To the Editors of the Ceylon Observer.

DEAR SIR,—Perhaps the following remarks on the subject may be useful in answer to the question put by "Quinine" in your valuable paper on the 30th ultimo:—

In the first place, the barks known in England as cascarilla and cinchona are two totally different drugs, having perfectly distinct botanical origins. The word cascarilla is Spanish for "little bark" (as shown by yourself in your foot-note), and was the name given by the Peruvians to the cinchona barks, the collectors themselves being called "Cascarileros" or "Cascadores," and when the cinchona barks first found their way to Europe, this name came with them.* This, according to Sir G. Baker, was (in the case of England) about the year 1655. About the same time, or shortly afterwards, the bark of one or more species of Croton was brought to Europe from the Bahamas, under the name of Eleuthera bark, and was prescribed by a German physician as a febrifuge, and very soon afterwards it began to be *confounded with cinchona barks,* and to be used in place of that, then rare, medicine; hence the name cascarilla which was erroneously applied to the Bahamas bark, until at last it quite superseded the original and more correct appellation of Eleuthera. In the Bahamas, the name cascarilla is still hardly known, the bark being there called Eleuthera bark, or Sweet Wood Bark. It is used as a medicine, is the essential ingredient in most fumigating pastilles, and is frequently smoked with tobacco for the sake of its corrective odour. It is shipped from Nassau. New Providence (Bahamas), and is usually packed in sacks. The quantity imported into the United Kingdom in 1870 was 613 tons, valued at £16,482 (Flückiger and Hanbury's Pharmacographia, Macmillan & Co., London 1874).

The barks, therefore, stand thus:—

Cascarilla bark, bot. origin, Croton Eluteria, nat. order Euphorbiaceæ, known in England as Cascarilla, and in the Bahamas as Eleuthera bark.

Cinchona bark, bot. origin, various species of the genus—cinchona, nat. order Rubiaceæ, now known in England as cinchona, and in S. America as Cascarilla or Cinchona bark.—Yours faithfully,

J. P. T.

Kandy.

THE JACK FRUIT TREE.

TO THE EDITOR.

SIR,—INQUIRER in your issue of the 2nd instant asks for some information about the jack fruit tree. It is not true that a plant, reared in the nursery and transplanted will yield bad fruit or fruit sparsly. This probably has originated in the native mind from the fact, which I have experienced and borne out by friends in the planting line, that a plant from a seed sown where the tree is to grow, springs, up more vigorous and comes into bearing sooner than a transplanted seed.

In my farm about five miles from Bangalore, I have nearly a thousand seedlings of different ages and growths, and I have found that it is better to place the seed in the ground—a seed sown this way will in twelve months be nearly double the height of a seed of the same age grown in and transplanted from a nursery. In the nurseries about this part the jack seeds are put in pots to allow of easy removal, this induces the tap root—which in the jack is strong, vigorous, and very sensitive of opposition—to curl as soon as it touches the bottom of the pot, and it takes some time after it is transplanted to *coax* it to continue its downward path. Herein lies the secret of the growth of the ground sown seed over its nursery brother; the former striking down at once continues without any interruption to penetrate the subsoil, and is more capable of yielding that nourishment which is conducive to speedy growth and vigor.

Though INQUIRER may have been successful in transplanting jack plants, as a rule it ought to be avoided; let him try the experiment of sowing a seed in the ground. Dig a hole say one-and-half foot square and two feet deep, fill with a mixture of good manure and sand, sow the seed about two inches below surface and water once a day; if his *malee* does not rob the seed to eat it (the natives being very fond of it boiled or roasted) in about 12 months he ought to have a good healthy tree about 2½ feet high. Jacks bear in their sixth year.

In the coffee district of Nuringabad the jack is a fine tree, and the fruit of it there is much appreciated. Major-General Otily, a well-known coffee planter, planted out a dâk road with an avenue of jacks, the seeds were all ground-sown in the spots they were intended trees should grow; and this avenue is one of the sights of the locality—the general never potted a jack seed, and since I have known him, I have followed his example with benefit to myself.

There is one description of jack to be found in Bangalore, which produces fruit on the root below the surface of the ground—this is highly prized, whether it is a freak of Nature or not, I cannot say, but from the very paucity of such trees, I am inclined to think it is not a distinct species.

Natives hereabouts will tell you that the following is the most correct way to grow a jack tree. Dig a large hole about 5 or 6 feet square, take a *full* fruit quite ripe, and without cutting it, place it in the hole, filling up with manure and sand, the fruit should be about three feet below the surface. In about two months *one strong* plant shoots up, and this will be an extraordinary good plant as far as the quality and quantity of the fruit goes. It looks absurd on the face of it, but nevertheless a friend of mine was induced to try it, and I need not say it was a complete failure.

THOS. T. LEONARD.

Bangalore, 13th February 1880.

DOD ROGA.

TO THE EDITOR.

SIR,—Can you, or any of your readers, tell me the best remedy, and how to be administered, for "Dod Roga" which is now somewhat prevalent in the district, introduced from Mysore by the cartmen thence coming to carry down coffee. The natives say that the disease is incurable and do not attempt a cure but leave the sick animal at once.

INQUIRER.

Mercara, Coorg, 16th February 1880.

IRRIGATION.

To the Editor Hindoo Patriot.

SIR,—I shall feel obliged by your inserting the following remarks on an article which will be found in your paper of the 26th ultimo, headed "*State wells in the North-Western Provinces.*"

First as to irrigation from wells which is usual in the North-Western Provinces.

In their vicinity, especially in the neighbourhood of those constructed of masonry may be seen broad tracts of splendid crops which would do credit to any country. But to raise sufficient water where it is from the surface entails great labor both for man and beast, and the machinery used in raising the precious fluid is costly and perishable.

When the rainfall is short, the water recedes in the wells and the ryots are frequently unable to lift it at all. At such time fodder is scarce, and the bullocks required for raising the water are, from want of proper food, weak and unequal to their task. To remedy these defects, some years ago I recommended pumps to the notice of the Court of Directors, and my suggestion was opposed by the Company's Engineers. But these gentlemen had probably not witnessed as I had done the mortality among the bullocks, thousands of them dying from sheer starvation. I am still of opinion that my suggestion would be a great improvement upon the present mode of raising the water, indeed in many places it cannot be done by any other means owing to the great depth at which it lies. I have said that the machinery used in lifting the water by bullocks is costly and perishable, this fact will be easily understood when I state that the *pool* is always made of leather, and in many instances the well rope is also of the same material, which from being alternately wet and dry soon wears out. A simple iron pump would cost but a small sum and when any trifling repair was necessary it could be done by the village blacksmith. Some long time since a Brahmin zemindar put one over one of his wells, and the people from the neighbouring villages flocked to see the "*kul*" at work much to their admiration and astonishment.

With regard to canals—if they convey water suitable for irrigation, and their construction does not interfere with the drainage of the country, such works in my opinion must always be preferable to any other. In them the cultivator has water without labour to himself or his cattle, and cultivation can be carried out on a much larger scale, because the ryot has only to lead the water in the direction required. No person acquainted with Indian agriculture will accuse the ryots of stupidity. They and the zemindars have their prejudices and so have English farmers. But once let the ryots be convinced that you take a real interest in their good, and that you are capable of giving sound advice, and they will not be slow in following friendly suggestions, for I have frequently found them willing to do so. When it is considered that almost the entire population of India is engaged in agriculture, it is marvellous how little has been done by Government for the improvement of the art. With a proper system of irrigation according to the requirements of the various parts of India, and with improved means of cultivating the soil, we should hear no more of famines. We might take a lesson from a neighbouring power, for no sooner had France determined to colonise Algeria, than a Committee of Senators was assembled to ascertain what products could be profitably grown in that country, and for one of the gentlemen of the Committee I drew up a paper detailing the mode of growing indigo and of preparing that valuable staple for the market of Europe and America.

I am Sir,
Yours obediently,
RALPH MOORE.

ESSENTIAL OILS.

TO THE EDITOR OF THE MADRAS MAIL.

SIR,—Can you or any of your readers give me any information on this subject?

(*a*) What is an *essential oil?*

(*b.*) Can fatty or resinous matter extracted from the leaves, petal, or bark of any tree, be correctly to called an essential oil?

(*c.*) Would it be equally correct to call the oil extracted from the seeds of, the same tree, an essential oil?

e. g. If an oil can be prepared from the rind, leaves, flowers, or seeds of any tree, which of these would be called or deserve to be called an *essential oil?*

Yours, &c.,
14th February. S. M.

☞ Our correspondent will find the most complete account of the essential oils in a paper read, in December 1863, by Dr. Gladstone before the Chemical Society. We subjoin the following extract from Chambers's Encyclopædia:—"The *volatile* or *essential oils* exist in most instances, ready formed in plants, and are believed to constitute their odorous principles. They resemble the fixed oils in their inflam-

mability in their solubility in the same fluids and in their communicating a greasy stain to paper or any other fabric; but the stain in this case soon disappears, and they further differ in communicating a rough and harsh rather than an unctuous feeling to the skin. Their boiling points are in almost all cases far higher than that of water, but when heated with water, they pass off with the steam—a property on which one of the chief modes of obtaining them depends. The oils have characteristic penetrating odours, which are seldom so pleasant as those of the plants from which they are obtained, and their taste is hot and irritating. They vary in their specific gravity, but most of them are lighter than water, and retract light strongly. Most of them are nearly colourless when fresh but darken on exposure to light and air; but a few are green, and two or three of a blue colour. By prolonged exposure they absorb oxygen and become converted into resins. By far the greater number of them are products of the vital activity of plants, in which most of them exist ready formed being enclosed in minute cavities which are often visible to the naked eye. Although diffused through almost every part of a plant the oil is especially abundant in particular organs of certain families of plants. In the *Umbelliferæ*, it is most abundant in the seeds; in the *Rosaceæ*, in the petals of the flowers; in the *Myrtaceæ* and *Labiatæ* in the leaves; in the *Aurantiaceæ* in the rind of the fruit. The members of this group which is an extremely numerous one (more than 140 essential oils being noticed in the article on that subject in *The English Cyclopædia*) admit of arrangement under four heads. 1. Pure Hydrocarbons; 2. Oxygenous Essential Oils, 3. Sulphurous Essential Oils; 4 Essential Oil obtained by Fermentation, Dry Distillations, &c."

The Indian Agriculturist.

CALCUTTA, MARCH 1st, 1880.

THE PLOUGH OF THE FUTURE.

AMONG the many suggestions which are being constantly made with a view to the improvement of agricultural operations in India, none we apprehend, are of more importance than those relating to the plough, and that this opinion is shared by the general public is evidenced by the fact that so many efforts are being made from time to time by various parties having the improvement of the plough in view. Besides the many private or semi-private attempts at improvement which have lately been made, notably those by Mr. Buck in the North-Western Provinces, and by General Angelo at the Hissar Farm, both of which we understand have attained a certain amount of success; there are at the present moment a few inventors before the public with ploughs which they have patented or are now patenting, and to those and their capabilities we propose devoting a few remarks. Before doing so, we would refer for a moment to the attempts being made in Southern India to introduce light English and American ploughs, which attempts also have gained success. We do not apprehend any permanent results of a beneficial nature to follow the introduction of those foreign ploughs, for many reasons, the principal of which are the following. They are two heavy from a drought point of view for the cattle of the country. The manipulation of the two-handed plough is found to be difficult of introduction, and the cost is too high. However good the ploughs may be intrinsically, the price places them beyond the reach of the mass of the people, and it is for them that the plough of the future must be adopted. We will enumerate what we consider ought to characterise this plough, and then see how far these requirements have been met by the ploughs at this moment before the public. The new plough thus must first (1) have the advantage of presenting to the rayat, as slight a difference in appearance as possible to the common country plough, which he and his forefathers have used for centuries. We hear a great deal of the conservative nature of the native of India, and while he is not perhaps so idiotic as to permit this feeling to stand between him and profit, it must be confessed that he does attach a deal of importance to change. He will not change until he is thoroughly convinced that the change is a beneficial one. All the American and English ploughs fail in presenting too great a change, and so do those adaptations of them which have been made in this country. The rayat has always been accustomed to guide the ploughs with one hand, and keep the other for the purpose of guiding the bullocks after his own primitive fashion, and he cannot be brought to use a plough which requires both his hands for the purpose of guiding, and thus compels him to provide a boy to drive the cattle. (2). It must be easily pulled. In most parts of India the cattle are miserably weak, and a plough to be at all successful must be well within the powers of those small cattle. The rayat is not yet sensible of the advantage on many considerations of improving the breed of his cattle, and although the Government are doing a little in this way, it is so little that centuries must elapse, before the Indian bullock is what it ought to be. We must then adapt the plough to the power available.

(3). It must be light in weight. The rayat has his superstitions on the subject of division of labour, and it does seem a little inconsistent that after a hard day's work from his bullocks, he sees no harm in making them drag the plough home to his steading, while nothing will induce him to impose this duty on his cattle in the morning. Hence we observe in the early morning, the rayat driving his cattle to the fields where ploughing is to be done, himself carrying the plough on his shoulder. For this reason the plough must be light, we have weighed Mr. Jones's plough and find it $14\frac{1}{2}$ seers. Mr. Chick advertises his as weighing 17 seers, while Mr. Martin informs us that his plough will not exceed 11 seers. The specimen we saw and reported on briefly in our last issue was made, it appears, under certain disadvantages, and in a hurry, and moreover, wood not thoroughly dry was used, hence its abnormal weight of $18\frac{3}{4}$ seers. All of these seem to come within the limit of a man's carrying capacity.

(4). The ploughman ought to be able to reach the bullocks' tails, we need not waste words here dilating on the percentage of Indian bullocks which have got broken tails, nor as the heinousness of the cruelty which has brought about this excessive amount of caudal fracture, but must take things as we find them, and this we must take for granted, that the Indian rayat *will* twist his bullocks' tails, and if we can make a plough which admits of his doing this without any undue effort on his part, it may after all tell us the bullock in the form of a less aggravated manipulation, Jones's plough and Martin's also can pass muster on this score. We have not yet seen Chick's, but doubt not that the inventor's experience has told him this important requirement.

(5). It must be so simple in construction that any ordinary village *mistree* may be able to repair it. The importance of this will be at once apparent to any one who has lived in the mofussil, and has seen the work performed by a village carpenter or blacksmith. The latter are usually very ingenious artificers and manage to turn out a fair job with the most primitive tools, but the former is a most clumsy workman, whose head does not seem capable of entertaining a new idea. It is then incumbent on us, if we would make the plough really popular, to have it so little foreign to the village *mistree's* ideas of what a plough is, that he will have no difficulty in repairing the implements from time to time, and even in making entirely new portions such as share, mould-board, or coulter. Mr. Chick affirms that his plough will stand this test, as we know the other two will.

(6). It must be durable. The rayat is poor, and it never occurs to him to have two ploughs, unless he has two sets of oxen at work. He never has a spare plough to put to work when an accident takes place, consequently if his plough gets broken, he must wait until it is repaired. The plough then must be durable and strong, and must be such, that having paid for a new one, he will not be called on to repeat the purchase for a considerable time. This is a qualification which cannot well be judged by a mere glance at a new plough, unless we may be allowed to predicate durability, from the absence in the plough of those elements likely to lead to premature decline in this connection, such as inferior workmanship, or the use of cast iron, which latter is frequently liable to give way should a sudden strain be put on it, such a sudden wrench as would be communicated to the framework by its suddenly coming on a large rock or a stubborn root. Mr. Jones's plough will we imagine stand this test, as certainly will Mr. Martin's, as it contains nothing but the finest wrought iron and steel. We observe that Mr. Chick's has some cast iron used in its construction. We have no desire, however, to speak dogmatically on this point, as we have said, we have not seen the implement. In a general way we deprecate the use of cast iron in an implement of this sort.

(7). It must do more and better work, than the common country plough. This is a truism, a new invention must be an improvement in its capability for work, else why introduce it. How then will these new ploughs stand, when tested by this. The only plough we have actually tried is Mr. Martin's, and as to its power to do more and better work, there is no possible room for doubt. The ordinary method of ploughing with the common country implement is to go once over the field, scratching the ground to the depth of an inch or so, then repeat the process going half an inch deeper, and this deepening process has to be repeated four or five times, so that the amount of work a plough can do in a day, is reduced to one-fifth by the work having to be done over and over again. Mr. Martin's plough on the other hand does its work quite as quickly, with no more strain on the cattle, and to such a depth that one ploughing is enough. Hence time and labour are economised. We cannot speak of the other two from personal experience. Mr. Jones says his plough is becoming popular on this very account. It gives no trouble, and does its work thoroughly, and Mr. Chick affirms the ability of his plough to do thirty per cent. more work on the same expenditure of labour and money.

(8). It must be cheap. This is perhaps the most important feature in the plough of the future, and is the reason why so many inventions fail to satisfy the want. They all err on the side of cost. Those three of which we have been speaking are much cheaper than many that have been presented to the public. Mr. Chick's we see advertised at Rs. 10 complete. We are just afraid this will be found too expensive, we do not mean relatively, as it may be well worth the money, but we fear the amount is more than a native will give for a plough, however good. Mr. Jones's plough sell at Rs. 5-8 at Cawnpore where it is made. This is more within the reach of the rayat, and we are therefore not surprised to learn that this plough is selling well. Mr. Martin proposes selling his at Rs. 3, in the Upper Provinces, or say Rs. 4, in Calcutta. He anticipates a good sale, as soon as he is in a position to place it on the market, but this he cannot do till he secures it by patent, and, like many other legal details in this country, the taking out of a patent is rather a tedious process. These gentlemen will deserve well of India if they succeed as they anticipate, as they will have solved the problem of making two blades of grass grow, where only one grew before.

SOME OF THE PRINCIPLES UNDERLYING THE ROTATION OF CROPS.

ON a former occasion we said that there are three methods at present in practice for the purpose of maintaining and improving the fertility of the soil—these are fallowing, rotation, and manuring. The last, we have considered shortly, and we now purpose briefly noticing the principles underlying rotation.

By rotation is meant the succession or recurrence of cert crops, spread over a longer or shorter period of time, in such a way that crops of the same kind may be separated from each other as far as the length of the course will allow. The principle underlying every rotation, every course of cropping, is this—different crops require different foods, and those which withdraw from the soil the same mineral constituents should recur at as long an interval as possible, in order that the special plant-foods required by each may have time to gather in the soil, by the natural processes of disintegration and decay.

When different plants are grown on the same land several years in succession, the first of which leaves behind in the soil plant food which the second may require, and the second, that which the third may use up, then all other conditions being present, the three different crops are likely to be profitable ones without unduly taxing the natural resources of the land and we have what is called a rotation of crops.

A thorough acquaintance with the ash constituents of plants lies at the root of all rational rotation. There are certain mineral constituents such as iron, manganese, &c., which occur in such small quantities, that for all practical purposes they may be disregarded in any estimate of ash constituents. There are others which though not present in great abundance, are nevertheless essentially necessary for the building up of special plants. Here's an example of this: Grasses, indeed all the *cereals*, are notable for the large quantities (comparatively speaking) of silica they contain; and where the amount of soluble silica is small in a soil, the exhaustive effects of crops of this kind soon make themselves apparent. The continued repetition of crops of this kind would render their profitable cultivation impossible, even while at the same time other substances might be present in sufficient abundance to produce highly profitable crops of other plants, which do not require that substance in such abundance. Beans, pease, turnips, hay (especially the latter) require large quantities of alkalies such as potash, and may be grown with an infinitely small quantity of silica. If the straws of cereals are returned to the soil, cereals are probably by far the least exhaustive of all cultivated crops. This is no doubt the reason why straw should as far as possible be consumed on the farm on which it is raised. Liebig has estimated that oats contain 33·42 per cent. of phosphoric acid, barley 22·74 per cent., wheat 19·38 per cent. If in a rotation oats were taken first and the other two followed, probably the last crop would be less than an average one, because of the exhaustive drain on the phosphoric acid contained in the soil. Some plants have deeper roots than others, and so can bring up from greater depths the special plant-foods they require. Others have roots which ramify through a larger area of soil, and are in the soil a longer period than others (autumn sown wheat in England). Some again have a much larger leaf surface than others, and are thus able to draw a large store of food from the air. It is highly probable, that near the sea or on land over which winds from the sea pass, plants obtain small quantities of soda, potash, common salt, and other compounds. In this we have probably one of the reasons (the chief being of course the

difference in plant-food) why root crops follow grain crops, the roots and foliage of each crop penetrating the soil and spreading themselves in the air in a fashion characteristic of each.

Some plants are cultivated for their seeds; others for their roots, or for their folliage, or for the coloring matters they contain or the fibre derived from the stalk of their seed pods. Crops of roots folliage and seeds may thus naturally be supposed to alternate with each other to the best advantage.

In Sweden, when pine forests are cut down, a growth, not of pines but of birch follows. The difference of the ash constitutents is said not to be sufficient to explain this, if not, then the difference of the root ramifications may in part account for this change of vegetation ; taken of course along with the fact, common among plants as among animals, that there is always going on a struggle for existence in which that plant or animal which finds the greater number of conditions suitable for its growth and propagation, drives out all the others from the same area or *habitat* more or less completely. After the great fire in London, 1066, large quantities of *Erysimum latifolium* grew up on spots left bare by the fire. The houses of that period were chiefly composed of wood, and no doubt the ash constitutents washed into the soil by rain furnished large quantities of potash available as plant food ; and thus provided one of the conditions for the growth and spread of plants which on account of their former rarity escaped notice. At Copenhagen the *Blitum capitatum* appeared in the same way after a fire ; and at Nassau the *Senecu viscosus*. In America when pine forests are burned down, poplars grow up. In most fields in Britain which have been long in pasture or *lee*, a species of *Seneco* with the characteristic yellow flowers clustered close together, makes its appearance in such quantities as at a distance to give a yellow colour to the greater part of the field, these are probably due to the slow gathering in the soil of potash. There can we think be no doubt, that the presence of certain indigenous plants on land, point to the existence of certain constitutents in the soil, as well as to the physical properties of the land where they abound ; and it is only necessary to change these conditions by drainage, deep-ploughing, and burning ; and the liberation and removal of potash by liming and appropriate crops, to change materially the indigenous plants of some districts, at all events in cultivated land. The whole question of the relation of indigenous vegetation to land and how faithfully it may indicate the existence of certain plant-foods and mineral constitutents, as well as physical properties in the soil has as yet scarcely obtained the attention of trained observers which its importance demands. We think there is here a very wide and interesting field of study in which the botanist, the chemist, and the agriculturist may each gather useful facts.

The following we believe may be taken as established.

1st. The absolute quantity of inorganic substances removed by plants varies, not only, with the crops grown, but also with the part of the plant.

100 lb. of wheat seed after burning leaves	2 lb.
„ „ „ dried clover hay	7 „
„ „ „ turnip bulb...	7 „
„ „ „ leaves of cabbage	26 „

2nd. Different crops, though requiring for their full growth all the mineral substances found in fertile soils take those into their tissues in different proportions. Root crops require large quantities of potash. Clover uses lime in considerable quantities ; and grain, especially wheat requires phosphorous in considerable abundance.

3rd. Different parts of the same plant take from the soil different quantities of inorganic substances.

	Potash.	Phosphoric Acid.
Wheat grain	30·02	46·79
„ Straw	17·98	2 75
„ Chaff	9·14	4·31
Oats Grain	20·68	50·54
„ Straw	19 46	5·07
„ Chaff	6·33	1·04
Turnip seed	21·91	40·17
„ Bulb	23·70	9·31
„ Leaves	11·56	4 85
Mangold root	42·73	12·31
„ Leaves	8·34	5·89
Potato tuber	48·8	8·61
„ Stem	39·63	6·68
„ Leaves	17·27	13 60
Kohl rabi bulb	36·27	13·45
„ „ Leaves	9·31	9 43
Cabbage head	40·86	12 53
„ Stalk	40·93	19 57
Tumothy grass	31·09	11·29
Rye grass	28·99	10·07
Cock's foot	29·52	8·60
Alopecurus	37·03	6·25
Red clover	25·60	4·09
Cow grass clover	22·78	4 94
Yellow clover	27·48	——
Rib grass	33·26	7·08

Anderson.

From a consideration of the ash constituents of different parts of the same plant, such as that given above, it is quite apparent, that a crop may at one period of its growth thrive vigorously, then fall away. Wheat may have a magnificient straw, but the grain may be much below the average weight ; because there is abundance of silica, and phosphoric acid may be deficient ; or again, this may be reversed. The straw may be poor and very weak, stunted in short, and yet produce plump full grain of more than average weight. We may also learn from this, why one soil or one district of country yields better crops of certain plants than of others. The necessary plant-foods may be in abundance or deficient.

4th. Plants of the same class, that is crops that withdraw plant-foods of a like kind from the soil should be repeated as seldom as possible ; and when it is necessary to return to them in the course of rotation, a different member of the class should be sown ; that is instead of repeating wheat, oats or barley should be preferred ; and turnips should be replaced by mangolds or some other root. There are crops which have a much higher commercial value than others, those it is the interest of the agriculturist to grow as frequently as he can ; this, however, can only be done within certain limits and with considerable caution.

BARODA AGRICULTURAL AND CATTLE SHOW.

(Communicated.)

THOUGH two months have now elapsed since the Agricultural and Cattle Show attracted the admiration of the multitudinous visitors at Baroda, it may not yet be too late to give some account of the event. Several casual notices of it appeared at the time in the local journals, but they were fugitive and fragmentary. It is desirable, therefore, that a consecutive narrative of it should find a place in a magazine conducted expressly in the interests of husbandry in all its branches. The Baroda show deserves to be duly chronicled not only on account of the benefits which such exhibitions confer on agriculturists generally, but because it was the beginning of a new phase in the administration of an important Native State, and the first of its kind ever held in the fruitful territory of H. H. the Gaekwar, and it is to be earnestly hoped that it will not be the last. It is the duty of all who are interested in the agricultural prosperity of India, to carefully study the results of such exhibitions, and if proved to be beneficial, to give them wide publicity for the encouragement of others.

The Baroda show was but one item of a long series of festive arrangements in connection with the marriages of H. H. the Gaekwar and his sister. This contributed to the number of visitors, but here the advantage ended. The distractions created by the other more popular events greatly lessened the concentration of attention and study which the show, had it stood alone, would

assuredly have received. This is greatly to be regretted. A thing of this sort, to yield its legitimate fruit, must be made a study by those who visit it, its objects carefully examined and compared, and all thought over on the spot. In the present instance there was too much hurry and restlessness, and too much desire to see everything everywhere. Had the show been the only object of attraction, it would have secured for itself more careful attention and fastened itself more firmly and more productively on the memories of its visitors. Still all disadvantages notwithstanding, the attendance was good, and the show of cattle and produce very fair. Taking the order of the prospectus we come first to.

HORSES.—There were 85 exhibited, and among these were some —in particular one—of the handsomest Katty horses ever exhibited in any horse show in Western India. This particular one is Reddo. He is a Katty Stallion, is a veteran at exhibitions and horse shows, and has gained the first medal or prize wherever he went. His great width of shoulder, finely formed legs, beautiful head, and above all, the strength of bone and muscle displayed, effectively dispose of all the recent cant about the inadaptability of Katty horses for heavy work. His scions, which were also exhibited, all more or less shewed some of his best points, but they are as yet too young to enable a judge to say whether they will develop into such animals as their magnificent sire.

Amongst Arabs the Stallion Anstey, the property of the Thakoor of Palitana, carried off the first prize, while General Graves, the veteran horse racer, came in for the second with his W. A. H. Pearl. Galloways and ponies were but sparely exhibited. The wedding festivities prevented a better show by local owners, their animals being largely employed in conveying them from one scene to another.

Before quitting the horses it must be added that one object which the Committee had in view in holding the show was undoubtedly attained. That object was to prove that horses of indigenous breed, if only cared for, are the proper horses for India, and that admixture of breeds generally ends in degeneration. Reddo, the Katty Stallion, was the admiration of all, and the much vaunted Arab, though worthy of all the praise he has received, rather sunk in estimation in his presence.

CATTLE.—What the horse is to the Arab Bedouin, the bullock is to the Gujerat cultivator. Mr. Kinlock Forbes, the author of Arnals of Gujerat, remarks that "the *Kunbi* and his bullocks are inseparable, in speaking of the one it is difficult to dissociate the other." The show of bullocks accordingly, in the heart of Gujerat, was necessarily good, but it was a matter of much regret that the bullocks of Dhrangadhra, near Abu, were not exhibited. These animals are really magnificent creatures. Their huge well-proportioned heads of curving horns, with large soft melting eyes, give them an appearance of the utmost imaginable good nature, while their immense bodies bespeak extraordinary strength and endurance. Handsome and strong, however, though these Dhrangadhra bullocks are, the Petlad district of the Gaekwar's territory can boast of nearly as handsome, and certainly quite as useful for all farming purposes. Several pairs from Petlad commanded high admiration. Of the 120 pairs exhibited, those of Petlad carried the first prize, and the only gold medal of the show, which was presented by H. H. the Gaekwar.

COWS.—Did not make a good appearance; of the 47 shown, there were but two poor and inferior representatives of the famous Ghir breed, which are so much valued in Gujerat. These cows have been known to give as much as ten seers of milk at one milking.

BUFFALOES.—The place set apart for these animals was the centre of unusual interest. The attraction lay in the massive bison-headed buffaloes exhibited by H. H. the Thakoor of Bhawnagar. In body they somewhat resemble the rhinoceroses, but the formation of their heads needs to be seen to be understood. These wonderfully constructed creatures seem to be *sui generis*, and so far the breed does not appear to have got into Gujerat. Their milking qualities are quite as remarkable as their bodily construction, for at a single milking they will give no less than 22 seers. These animals, of course, easily took first prize.

Male buffaloes made a good show. It was but natural that they should do so, for numbers of them are kept at the Baroda Court, well cared for and trained for fighting, which sufficiently accounted for the good condition in which they appeared.

Camels, asses, and goats, which were by no means well represented, must be passed over, and a word or two said specially about sheep. Bhawnagar, one of the most enterprising and go-ahead Native States in Western India, exhibited a pair of rams of the Liecester strain, which were only recently imported to improve the indigenous breed in Kattiawar. The appearance of these foreigners caused much merriment to native spectators, who had never seen the like before and were almost sceptical about their being sheep at all. They looked like a pair of huge pillows propped up on four little white sticks, so round, and puffy and soft were they. The wool was nearly a foot long, and did not grow below the knee. It is to be hoped that they will become acclimatised and add to the value of Indian wool in the future.

POULTRY.—This department of the show was, to a considerable extent, shared in by the European residents of Baroda. Cocks shows of curious rare breeds, geese from Venice, ducks from Suez, and turkeys from unknown regions formed a distinct and lively colony in the grounds of the show. Pigeons of all kinds and of all manner of plumage greatly contributed to the ornamentation of this interesting feathered settlement. The crops were expressly designed by Major Nutt. They surrounded a group of umbrageous trees, a series of concentric circles extending to the utmost limit of the shade, and, barring the little incidents of dispute and tyranny which at times occur even in more refined society, looked altogether a very happy community.

VEGETABLES AND FRUITS.—The products of numerous gardens in and about Baroda contributed largely to the vegetable show, while very fine samples of fruit came in from outlying districts, even as far as from Bhavanagar across the Gulf of Cambay. The oranges from Bhavanagar, which were equal to the best of their kind produced in any part of India, carried the first prize, pomgranates and guavas claimed much attention, while the enormous bunches of plantains which loaded the stalls caused wonder and amazement. Some of these gigantic branches bore each a weighty mass of 150 fruits. Fruits of various other descriptions were fairly well represented, and in the general opinion of the judges the show in these products was quite a success.

GRAINS AND SEEDS.—This branch of the show was the best; grains of all kinds and from nearly every part of India were exhibited. As this is probably the most important department of any agricultural show, a somewhat fuller account of it will readily be pardoned, though it is not necessary to note every kind of grain that was shown. The maize or India corn came in from Kattiwar and Gujerat, and from the greater distances of the Punjab and Cawnpore. The Punjab shocks carried the first prize. They were grown from American seed, and the India growth was as good as its Western parent. Each grain was fully three-fourths of an inch long and broad in proportion, while the colour was exceedingly white and glossy.

Of wheat there were 30 exhibits. Cawnpore took the first prize for a very fine, white, and well shaped description, and Petlad, in Baroda Territory, took the second for an article of almost equal value. In 33 exhibits of grain, Dr. Macdonald stood first an enterprising land-owner of Nariad in the British district of Kaira, stood second. *Jowari* had 43 representations, but neither Kattiawar nor Gujerat was able to compete with Khandesh a farmer from which locality taking both the prizes offered.

The prizes in *bajari* were taken by Petlad and Bhavanagar from 37 competitors. Rice was exhibited by 94 persons. Petlad was awarded the first prize, and the other two to Bombay and Karri, in Baroda Territory. Paddy or rice in husk, was shown in numberless varieties, some 25 samples being put forward by a single farmer from the sea coast near Bombay.

The prospectus, however, unfortunately did not provide any prizes for this article.

In oil seeds Baroda stood unrivalled and carried off most of the prizes, while it failed in *Til* and *Nachni*, two products of some importance. Petlad carried the palm in respect of grains, and was very properly awarded the silver medal. Nariad in British Territory, and Dr. Macdonald, of the Bombay Gardens, were the next in general merit.

Tobacco is very largely cultivated in the Petland district of Baroda State, as it is also in the neighbouring British district of Nariad, and the competition, therefore, was very keen. To the discomfiture of all other competitors, however, Major Nutt

carried off the first prize by his splendid growth from Kentucky seed. The size and appearance of the leaves of this foreign plant filled the local tobacco planters with wonder and delight, and the great demand that ensued for the same kind of seed was one of the evident fruits of the show. It is surely matter of regret that such fine tobacco bearing soil as lies in abundance in Gujrat should not produce an article far superior to what is now grown in the locality. To show the interest taken in tobacco growing, it is only necessary to say that there are no less than 193 exhibits, green and crued together. The other prizes offered were shared between the two districts already named.

COTTON.—This article caused much excitement, which was engendered not merely by the high value of the prizes in the prospectus, but also by the feeling that the credit of each exhibiting district was more or less at stake. Ginned and cleaned together, there were 124 samples shown. Bhavanagar, Baroda, and Khandesh took the chief prizes. Bhavanagar took also the first prize for cotton seeds and for growing plants. The staple of some of the Bhavanagar cotton was all that could be desired in length and strength.

In sugarcane there was a contest between Bhavanagar and Baroda, which ended in a draw, the former getting the first prize for indigenous and the latter for the Mauritius article.

Fibres, though not generously treated in the Prospectus, made nevertheless an excellent show.

There is a sample here at present, taken from the Malachra plant, which for length, gloss, and fineness is unequalled. The Government of Bombay are endeavouring to make the growth and manufacture of this article as popular as possible, and should they succeed, a vast trade in Malachra may confidently be prophesied. Manufacturers in Europe, if made acquainted with this article, would doubtless turn it to good account. The fibre has only recently been discovered by Dr. Grey, of Bombay and is not yet very generally known.

The show closed with what ought to have been a most interesting event, namely a ploughing match. Fifty ploughs were placed in position, and at a given signal all started and worked for 40 minutes. The large crowd of natives who had assembled to witness the work showed how deep was the interest taken in this department of the show. Unfortunately, however, the ground selected was not at all suited for the exhibition, which was one of the many instances in which Major Nutt's untimely accident proved a serious drawback. The greater part of the soil was so hard that ordinary ploughs could not enter it, and one or two were broken in attempting it. In several plots the native implement made no more impression than a walking stick would have done, the marks on the surface being scarcely discernible. Even the lately introduced light English ploughs were powerless in breaking the crust. In some plots which had been watered the day before the work was fair enough. The only plough which, in the unwatered plots, went into the soil and honestly turned it over, was a large heavy one of English make. The defect in this instrument was its great weight, requiring two pairs of bullocks to drag it along. But notwithstanding its handicapping by the extra pair of bullocks and extra men, it gained the first prize, as from the thorough nature of the work it performed it well deserved to do. The great fault of the native plough is that, the share being only a narrow rib of iron and there being no mould board at all, it takes at least three ploughings to break up all the soil, while the English instrument, when properly handled, turns over the whole soil once for all.

Among the ploughs which competed there were four from Europe, manufactured by Messrs. Ransomes Sims, and Head, and there were two from Benares, manufactured by Dr. MacGregor of the Central prison there ; there was one also from Cawnpore, sent by Mr. Crawbey, but none of these, though pronounced by competent judges to be first class articles, were fit to cope with the hardness of the soil. In ordinary ploughable land they would have done well, but in this instance their performance was little better than that of their native rivals. The winner of the first prize was made by Cooke, and has been in use for some years on an enterprising Parsee's farm in the neighbourhood of Baroda.

To say that Agricultural shows are beneficial in improving the art of husbandry and developing the resources of the soil, is a truism, and nowhere more than in India is such improvement needed. In the course of this paper, mention has been made of Bhavanagar and Kattiwar as having taken away many of the prizes. This fact is a proof of the advantages of shows within our own observation. Major Nutt, who spent some years in Kattiwar, inaugurated, seven or eight years ago, agricultural shows in that province, and the people from witnessing them have learned to improve their stock and produce, and to give greater attention to cultivation and manures. Hence their superiority in almost every department of the show at Baroda, and who shall say what seeds of improvement this show may not have sown in the heart of Gujarat ? The inquisitive curiosity displayed by numerous cultivators is itself a sign that new ideas had already been started in their minds, and among an uneducated and simple peasantry, the birth of a new agricultural idea should be viewed by the administration as of at least equal importance with the birth of an heir to the throne.

It is deeply to be regretted that Major Nutt, the enthusiastic agriculturist and the author of this and several other shows elsewhere, was confined to his couch all the time of the exhibition. His organising powers are well known, and though by his forsight and general arrangements there was no appreciable hiatus in any part of the plans, yet his absence was felt everywhere as if something was wanting that ought to have been present. Indeed the details of the work could not have been carried out with anything like success, had it not been for the great energy and indefatigable exertion of Mr. J. A. Raitt, the Honorary Secretary, who gave himself heart and soul to the complicated business, and made the show a memorable and fruitful event in the history of Baroda.

R.

EDITORIAL NOTES.

THE subject of well irrigation has lately been taken up by the Government, and it acquires a degree of importance when we attempt to compare the cost of irrigation by well with the same operation by canal. From calculations based upon the estimates made by parties well able to deal with the subject, it was found that irrigation from wells would entail an annual charge of 9 annas 8 pies per acre, *plus* the actual expense to the cultivator of raising the water. As he has his bullocks on the spot, and does not place a high value on his time, we might safely reckon a charge of Rs. 2 per acre as an ample one to allow. From the report on irrigation in the North-Western Provinces and Oudh for the year 1879-80 (kharif crop only), it appears that the assessment on account of water-rate was at the average rate of Rs. 3-2-3 per acre, and this, be it remembered, was for the kharif crop only, the extent watered by the canal having only been 555,641 acres, or the merest fraction of the cultivated area. That the high rate charged for this canal water acts as a deterrent, is shown by the fact that the income realised by the department depends largely on the rainfall for any given year, and as it is of the utmost importance that a judicious use should be made of this water, it is thought that the canal water should be supplied not only to those who choose to use it, but that all whose fields are within the reach of the water should be taxed for it. The cultivator will not spend one rupee in the hope of saving ten, he will only make the outlay against a certainty; hence the advisability of making the canal tax a compulsing one, payable by all who have water within their reach. When a district neglects to use it, and a partial or total failure follows, the Government have to step in with help, and it is better that the Government should interfere to prevent than to relieve.

THE Calcutta correspondent of the *Indian Herald* makes the following remarks on Mr. Martin's plough :—

Agricultural Exhibitions in India go a greater way in developing the productive resources of the country and in lending an impetus to the extension of trade, than even the spread of railways and other means of locomotion. While the latter facilitate the distribution of the produce of land over a large area, the former conduce to improve both its quality and quantity. Those who have watched

the conservative spirit that pervades the lives of Bengalis will not fail to remark how slow they are in adopting any deviation from established usage. The rude implements of agriculture used by their ancestors centuries ago, in tilling the land or threshing out corn, are retained to this day with the same results—*viz.*, great waste of power and produce. But it is to be hoped a revolution will shortly be effected in that way; thanks to the enterprise and energy of an English gentleman who hails from Etawah. Mr. W. Martin, planter and talookdar of that place, exhibited an improved plough at the Agricultural Show held at Krishnaghar on the 14th instant. Although it is a compromise between the ordinary country and the English plough, its combined advantages are admirably suited to the requirements of the peasant, who can easily work it with the cattle commonly employed in these parts. The judges who awarded the prize, report that it makes a deeper furrow, and consequently turns over the soil better than the country plough. It is pronounced to be more effectual and just as cheap as the other. In point of efficiency, cheapness, and simplicity (for a village blacksmith can mend it) Mr. Martin's invention ought to recommend itself to the notice of the Bengal zemindars.

THE annual ploughing match at the Sydapet Farm took place on the 19th December 1879. The competitors were divided into two classes, one consisting of the students in the School of Agriculture only, the other open to any one. In awarding prizes the following values were placed on the character of the work :—

Depth ...	...	...	...	30
General Finish	...	...	...	30
Straightness	...	...	...	25
Speed ...	...	...	...	15
			Total	100 points.

In the class open to all, twenty-six competitors entered, and as a proof of the general excellence of the work done, the first prize was gained by a ryot working with an English pattern plough, and he scored no fewer then 95 points, a good second scoring 84 points with a Swedish pattern plough, followed by 81 points made with an American pattern plough.

Nine competitors entered for the school prize, although the points scored were not so good as in the other class, the highest score being 85. We are not informed what particular plough was used.

These matches are valuable as putting to the test the alleged merits of certain ploughs, and certain methods of working. At the present time agricultural subjects are engrossing a considerable amount of attention, and we think the Government are badly advised when they attempt to throw obstacles in the way of new experiments and inventions, having for their aim, the improvement generally of our agriculture. We hear, for instance, complaints made by inventors, that they have the greatest difficulty in getting their inventions secured by patents; that they have to dance attendance for months at sundry Government offices, and thereby lose valuable time, and that the whole proceeding seems to go on the assumption that they are soliciting a great favour instead of asking a right which they are willing to pay for. These things disgust men, and lead them in many instances to imagine that the Government really do not want to encourage invention and improvement.

THE report on the working of the Lucknow Horticultural Gardens for the year ending 31st March 1879, has just been issued, and it is, as usual, accompanied by a short order from the Government, N.-W. Provinces and Oudh, which is a model of what such an order should be. It is short, but sufficiently long to touch on all important topics, and we observe with much satisfaction, that this order embodied in a letter from the Secretary to Government, N.-W. Provinces and Oudh, to Mr. E. C. Buck, disclaims all idea of interfering with details. This is exactly the duty of the Government. The whole subject being in the hands of responsible officers, who are *primâ facie* supposed to be well up in the subjects under discussion, it is wise of the Government, whose information cannot be expected to be special, to leave the carrying out of details to those best qualified. This, we must confess, is unusual, and we therefore have the greater pleasure in commending it. Mr. Ridley is highly spoken of in the order, and this commendation is all the more creditable to him when it is remembered that he succeeded such an expert as Dr. Bonavia, whose mantle seems to have fallen on the shoulders of his successor. We are also pleased to see that the financial returns are considered satisfactory, although the expenditure is nearly Rs. 1,900 over the income. This is a second fault often committed by Government in connection with these institutions, the measure of success which attends them is supposed to be gauged by the balance at credit at the close of any given year.

A most important series of experiment was initiated with the view of ultimately improving the indigenous or acclimatised kinds of fruit. This is a step in the right direction. Our efforts are too often wasted in trying to introduce exotics when the country produces in abundance a large variety of fruits which are well adapted to the climate, and which only require some intelligence in the way of cultivation to improve them and make them a source of wealth to the country. The same plan has been followed with respect to vegetables and flowers. In the former, a considerable amount of success was attained, which speaks well for the future vegetable supply of Oudh. Nor was arboriculture forgotten, several attempts having been made with the different varieties of the *Eucalypti*. We look forward to valuable results of the operations at this institution, which is evidently under careful and intelligent management.

" AN expert in Indian teas states in a home paper that the chief drawback to their extended consumption in England, is the fact that they speedily deteriorate and will not keep. This is attributed to the insufficient drying of the leaf, or the use of machinery in the rolling process." So says the *Pioneer*. It is undoubtedly true that Indian tea, as now made, will not keep, and this is quite a new defect in Indian tea. Time was when tea was not considered good until it was a few months old; some brokers even insisted on one year's keeping as necessary to mature its flavour. When the Suez Canal was opened, many planters imagined they would not get full value for their tea, on account of its being placed on the market, too soon after manufacture. About the middle of last year, a few chests of tea were found in a godown in Darjeeling where they had lain for several years, and had been quite over-looked. They were opened under the suspicion that the tea would have gone bad from old age. The result, however, was quite different; the tea was found to be so mellowed as to be simply delicious, and it was readily sold on the spot at fancy prices. Now such a thing could not possibly happen under existing circumstances. At home, a buyer finding the market favourable, lays in a good stock for future requirements, and finds it getting worse and worse as time advances. He imagines, like the expert above referred to that it must have been insufficiently dried, or that the machinery has got something to do with it. He forgets, or perhaps, like our expert does not know that had the tea been insufficiently dried, it would not have kept a month. Within that time it would have become quite mouldy, and he ought to have known also that the rolling by machinery could only affect the shape of the tea, but could have no influence on its chemical condition. Its influence could only have been mechanical. The true cause of this deterioration we believe to be the present ruinous method of manufacture. For the purpose of making the tea of this country suitable for mixing purposes, and of giving it the necessary pungency to make up for the want of flavour in the China tea with which it is mixed, the process of manufacture is not carried out in its entirety. At a certain stage of fermentation, this process is checked. And more, the good old method of panning is almost entirely abandoned, entirely so, in fact where the brokers' influence is felt. The panning was resorted to in order to tone down the bitter flavour natural to the tea, and the checking of fermentation which to a certain extent assimilates the manufacture of black tea to that of green, has the effect of producing a thick malty liquor, with a hoppy flavour. On a sample being "tasted " the liquor is found too strong and pungent, but the " outturn," the technical name given to the leaves after infusion, is found to be of a more or less greenish tint, instead of the almond colour, so much approved by those who love a cup of really delicately flavoured tea. This is the result of tasting, the after-result being that, after a time, this tea shows symptoms of decay because it is at best *cutcha* and imperfectly cured.

A QUESTION arose at the Bombay High Court last week as to the comparative effects of the datura plant and *bhang* (*carmalis moicus*) when administered internally. The Government Analyser was present as a witness, and expressed the opinion that the symptoms produced by both of these drugs in whatever form administered, were very similar, but could be readily distinguished by a qualified man. Two other points raised were, first, whether datura is daily taken by native women voluntarily as a remedy against sterility; and secondly, whether *bhang* is or is not taken in the form of a liquid. Strange to say no one in the court seems able to answer either of these questions, nor was any reference made to authorities upon the subject. The facts are, however, known to every native, the datura plant being prized for the virtues of the kind alluded to which its seeds are supposed to contain, and it is in frequent, if not common, use for this purpose. *bhang*, again, every native knows is taken as a liquid, being known by different names when used as a dry powder, or in other forms, of which there are several.

WE should like those who are interested in the improvement of native agriculture to see, as we have had the pleasure of doing, the "Patent Economic Plough" which has lately been invented and patented by Mr. W. Chick, 24, Chowringhee-road We have not yet seen the plough in actual operation, but a mere inspection of it seems to leave no doubt that it only requires to be made widely known to secure its universal adoption by native cultivators. We understand that it has been tried with striking success. The plough, while strong and durable and capable of deep ploughing, is so portable that the weakest plough boy could easily carry it to and from the field. It can be driven by one man, and may be drawn by a pair of small bullocks, such as are commonly used by the ryots. It is so constructed that while it ploughs deeper than the native plough, and with good bullocks will go to a depth of seven inches, it actually requires less exertion on the part of the ploughman than the native plough. He has to exert no downward pressure, but simply to guide the plough with one hand, while he drives the bullocks with the other. Such casual repairs as may be necessary may be executed by any village workman, and the plough is so simple that the ryot can work it at once without previous instruction. The price is only Rs. 11-8, and though a little dearer than the native plough, is surely within the reach of very many ryots, who, we are assured, would secure from its use a large profit from increased production. We are told that experiment has shown that, other things being equal, an improvement of 30 per cent. or more in production may be obtained. For the practical purposes of native agriculture this plough promises to be all that is required, while it is free from the objections which are fatal to the introduction of the English plough in this country.—*S. & F. of I.*

THERE are many directions in which the expenses of working English farms might be reduced, such, for instance, as placing the homestead in a central position, improving the arrangement of farm buildings, improving the roads upon a farm, increasing the size of fields, and so on. How often do we see the homestead of a farm placed without any regard to the situation of the land to which it belongs. Probably, the site was selected years ago, and for no reason that now possesses any weight. Of course the removal of a homestead to a new site is not an undertaking to be entered on lightly; it could be done only under unusual conditions. When the demands of modern farming call for extensive modifications in a homestead, it may well be taken into consideration whether, instead of incurring expenses in alterations, it would not be wiser to pull down such of the buildings as cannot be utilised, and to erect a new homestead in a more suitable position. In some instances, from the low position of the homestead, the farmer may be under the necessity of spending annually from 15 to 20 per cent. more on hand labour than would have been necessary had the homestead been placed where it ought to have been; and it is possible that the amount, if saved by the provision of a new homestead, would go a long way towards paying any extra charge that might be created in connection with the improvement. We all know how much more costly is the tillage of distant fields, than that of those conveniently near the homestead; the time of the horses and labourers is wasted on the road to and from the fields, while the cost of carting manure out, and the field produce home, is frequently very great. It is not always possible, nor indeed always desirable, that the exact centre of the farm should be the site of the homestead; but in the majority of instances it should be. It is very much the fashion now to construct imposing homesteads, and to group together the various buildings needed on the farm; and this is certainly an arrangement that enables the operations conducted at the homestead to be carried on with the least expenditure of labour, and under the most perfect supervision; but when the area of the farm is large, the cartages are lengthy, and therefore costly, if the manure must all be conveyed from one place, and the whole of the produce be carted there. On some farms out-lying stock-yards, with cattle-sheds attached, greatly facilitate the working of the farm in lessening the horse labour.

THE farm buildings are also often very inconveniently arranged. The homestead is the manufactory where the produce is worked up into a saleable form, and the various processes there carried on cannot be performed in an economical manner when the buildings are grouped together without any regard to the uses of each. The substitution of covered yards for open yards will effect much good, in enabling the work done at the homestead to be performed in the most economical way. Landowners who will carry out this improvement, and judiciously re-arrange the buildings when necessary, will do a great deal more for the good of their tenants at this unfortunate period, than by returning 10 or 15 per cent. of the annual rent, or even in some cases in reducing permanently the rent to this extent.

Farm roads, again, are seldom kept in the condition in which they should be, and the expense of cartage over them is usually considerably greater than on public roads. Of course the internal roads of a farm cannot be maintained in the condition in which public roads are kept, but there is no good reason why they should generally be in their present wretched state. The farmer who tests with a dynamometer the draught of his loaded carts on a public road, with that of his carts, similarly loaded when drawn over the ordinary roads of his farm, especially in a busy season and in showery weather, will have his eyes opened in regard to his losses from bad roads. We have found a cart loaded with a load of 1,000 pounds—a sufficiently hard task—on a farm road for a horse that could, in the same cart, draw with ease over a public road a load of 2,000 pounds. Of course, good roads will not help us when the carting has to be done over ploughed land, as in the case of the distribution of manure; however much of our farm carting is performed along prescribed tracks, which, though not in all cases recognised as roads, are used year after year for the purpose. Good internal roads would, on most farms, greatly reduce the expense of cartage. Not only should the roads be in a good state, but they should be so laid out as to reach the various portions of the farm by the most convenient and direct route. Some road-tracks on farms follow most tortuous courses, frequently following tracks originally made by stock in passing from one place to another. On many farms it would be the wisest course to abandon the present tracks altogether, and to strike out a few lines of roads where such roads are absolutely required, and to have them well made—that is, adapted to meet the needs of the farm. The construction of such roads, as well as their up-keep, would fairly fall to the share of the landowner, he getting his return for the outlay in the increased letting value of the farm.

There are many improvements that might be suggested to save expenses, but most of them require a considerable initiatory expenditure which the farmer, under the present system, cannot be expected to lay out, while the landlords will not. Yet a continuance of the depression that has forced so many of the latter to concede reductions of rent, would soon show that such expenditure would be real economy. Without it British agriculture cannot hope to compete with America.—*Statesman*

THOUGH the depressed state of British agriculture has engaged so much attention of late, there is much diversity.

of opinion as to the causes to which it must be attributed. That a succession of bad seasons contributed, in no small measure, to bring about the result deplored is evident. It is equally clear that it was the vast importations of cheap food from abroad—the United States chiefly—that kept down the price of agricultural produce in England, and that prevented our farmers from obtaining that recompense for short crops that, in former bad years, high prices afforded. But making every allowance for these influences, we do not think they could alone have brought about the almost entire collapse of British agriculture witnessed during the past few months, had it been established on a sound footing. Generally the remedies applied for the bad results of our husbandry are presents to the tenants from their landlords of sums representing 10 to 20 per cent. of the annual rent which the tenants have stipulated to pay. While we recognise fully the generosity which has influenced so many landowners in thus sharing with their tenants the losses of the past season, we cannot but deplore the fact that such an important interest as British agriculture, should have become so reduced as to depend for maintenance on the "generosity" of any body of men. But our faith in the capabilities of our country has not sunk so low as to admit of our believing that her agriculture need be bolstered up by such means. We are convinced that if our farmers had but fair play, their general practice would become so much improved that they would have no need to make any demand on the generosity of their landlords, and might defy all foreign competitors in supplying much of the produce of agriculture required by the people of this country. We do not admire the arrangement under which the land is generally owned by one class of persons and cultivated by another. We do not think it possible to draw up any lease or agreement that will protect the interests of the owner of a farm, and, at the same time, afford the tenant the protection he needs to justify him in working the farm to the best advantage, as long as farms generally are in the condition the majority of them are now in. We do not lose sight of the fact that, under the varied conditions under which agriculture is practised in England, bad farming is the rule. Landowners have but in a few instances performed the duty of putting their farms into a state thoroughly fitted for economical working, and, as long as this continues to be the case, it will be the best policy of the farmer to keep to the antiquated practice, and to incur as few risks as possible. High and modern farming demands a large outlay, but then the returns are proportionately increased; but the outlay required could not be safely laid out unless the farmer had his farm put in a thorough working state by the owner, or unless the farmer was himself the owner of the land, and carried out the improvements needed.—*Statesman.*

OFFICIAL PAPERS.

THE WYNAAD GOLD FIELDS.

FROM R. BROUGH SMYTH, Esq., Mining Engineer, to J. H. Garstin Esq., C.S.I., Acting Secretary to Government, Revenue Department, dated Ootacamund, 6th December 1879.

I HAVE the honor to submit the following report of my proceeding, during the month of November for the consideration of his Grace the Governor in Council.

2. From the 1st to the 6th of November inclusive I was employed in completing my general report and maps and, as already reported, these were forwarded to the Government on the 7th November. Subsequently my time was occupied in testing specimens of quartz and minerals, in treating amalgams, and in compiling a schedule of the yields of gold per ton of quartz from reefs and veins in South-East Wynaad and the Gardoor Ghât.

3. On Wednesday, the 19th, and on Saturday, the 22nd, I visited Nanjanad Valley.

4. On Tuesday, the 25th, I proceeded to Avalanche, and during the succeeding nine days examined that country and that at Sispara.

5. A map of these areas, now nearly ready, will be forwarded to you as soon as possible.

6. I am at present engaged in correcting the proofs of my general report.

7. I beg reference to the accompanying report on the country around Nanjanad, Avalanche, and Sispara.

ENCLOSURE No. 1.

REPORT on the country around Nanjanad, Avalanche, and Sispara.

Nanjanad.—It is not easy to indicate the areas which have been worked for gold, presumably by the natives, in the Nanjanad Valley. The quartz workings are extensive, and as they are found principally on land used for grazing, it may be supposed that they remain now very much in the same state as the miners left them. It is different with what may be called the alluvial workings in the old stream bed.

Though numerous evidences of the work done in former times are to be seen, they have been obliterated by the Burgher cultivators over an area whose limits cannot now be discovered. On my last visit the Burghers were engaged in levelling ground which had been sluiced for gold. The uneven surface was being made smooth and in course of preparation for sowing grain; and how many acres may have been thus treated cannot now be ascertained. Here in Southern India as in Australia the cultivator follows the miner; and a gold field that at one time afforded employment to thousands of persons becomes in a short time unrecognisable by its former inhabitants. The bright green crops of grain and the removal of the trees and scrub completely alter the character of the landscape and render it as unlike a gold field as any tract can well be.

It is certain that much work was done at one time by gold miners along the course of the stream which rises near the Belmont Tea Estate and flows thence through the Nanjanad Valley.

About one mile north-eastward from the Nanjanad Chuttram, there are outcrops of quartz which have been worked to some extent.

Prospecting operations have been carried on here during the last four months, but no quartz shewing gold visible to the eye has been found, and the results of experiments have been unsatisfactory.

Mr. Thomas Laing has washed several dishes of earth taken from the slopes of the hills in this area, and several have shown gold; and quartz pounded by him and washed has in some cases given a few particles of the metal.

In testing the stone by amalgamation several samples showed no gold, others yielded minute grains, but no weighable button was obtained.

The reefs are thick, some strike nearly N. 70° W., and all along the outcrops westward of the stream know as Buk-kan-halla there are old workings to be seen. The quartz is ferruginous, but the proportion of undecomposed iron pyrites is usually very small. Near the veins there are seams and nests of black oxyde of manganese intersecting the country rock and coating the quartz.

Strong "leaders" are thrown off towards the north, and these have generally a low dip.

Nearly one mile and-a-half west from the stream where these outcrops occur there are numerous heaps of quartz broken into very small pieces, and the excavations are large and deep. One sample of quartz from this locality yielded at the rate of 6 dwt. 13·47 grs. per ton, and another between 5 dwts. and 6 dwts. (a portion of the amalgam was lost).

These old workings are near what is said to be a perennial stream, and the quartz could be economically mined by adits. The locality is one which might be prospected with some certainty that the results would fairly exhibit the character of the reefs of the Nanjanad Valley.

The quartz is in most places white, but there is a proportion of brassy yellow pyrites, and much of the stone resembles that found at the Skull Reef near Devala.

Two dishes of earth were washed here and gold was obtained in both.

Avalanche.—After crossing the range about one mile south of the Nanjanad Chuttram, up to which point the country rock is intersected by well-marked large veins of quartz, there is a change in the character of the strata. Numerous very thin veins of quartz, nearly everywhere following the direction of the foliation of the rocks, present themselves, and not a reef is to be seen.

At Avalanche and near Kudiaked the strike of the rocks is N. 60° E.—S. 60° W., varying but a few degrees. They are quartzose, and a little magnetic iron is seen in places, but hornblende is rare. In the beds of the rivers rounded water-worn blocks were found very similar in composition to a basaltic rock; and here quartzose gneiss was got with minute foliated particles of graphite.

These were not traced to the rocks *in situ.*

In this locality also thin veins of quartz were observed running in the direction of the strike of the rocks, and there were intercolated masses of garnetiferous rock.

Though it was easy to collect specimens of pure quartz, no really persistent reef was seen; and it was soon evident that this was not a locality which would reward the prospector.

Mr. Thomas Laing made a cutting in the banks of a stream where there was a good "wash" and tested several dishes of the earth overlying the bed-rock, but no trace of gold was found; and many dishes of earth washed in other places gave the same unfavorable results. Quartz also was crushed and washed at various points, and not a speck of gold was discovered.

Sispara.—Careful attention was given to every feature in travelling from Avalanche to Sispara in the neighbourhood of Sispara, and thence down the ghât for some distance, but nothing was seen which would encourage the miner to search for gold; and though many dishes of earth were washed in the most likely places, no gold was seen anywhere.

About two miles and-a-half north-east from the mud-hut at Sispara the rock is composed of quartz and felspar in coarse grains, and closely resembles a binary granite; but where a weathered surface is observed, the lines of foliation shown by slightly projecting indurated veins composed mainly of quartz indicate a gneissoid structure. Again, down the ghât and elsewhere thick bands of ternary granite consisting of quartz, felspar, and black mica form the mass of the country rock; but these again are only intensely metamorphosed strata coinciding in direction with the ordinary foliated gneiss, and not true granite.

Where these bands occur, the detritus is exactly like that derived from granite, and where the rock has decomposed pieces can be picked up having a small specific gravity; they consist of a skeleton of silica (quartz), the more perishable associated minerals (chiefly felspar) having become kaolin or having dissolved out altogether.

On the edge of the plateau and in the jungle down the ghât several slabshaped pieces of white and crystalline quartz were dug out of the soil not resembling the quartz in the country-rock, but in these pyrites and oxyde of iron were absent, and no gold was seen in them.

Several dishes of earth were washed at and near Sispara, but not a trace of gold was found.

I returned from Sispara on the 4th instant, and I have not yet had opportunity to examine all the minerals and rocks collected during the journey; but there is no reason to believe that the tract lying between the southern part of the Nanjanad Valley and Sispara is likely to yield gold in quantities sufficient to remunerate the miner either from the masses of quartz (nearly everywhere granitic) or from the soils.

It may be mentioned here that some samples of quartz collected by direction of his Grace the Governor when his Grace visited Sispara yielded minute particles of gold by amalgamation. The locality as pointed out to me will be shown on the map.

Mining Engineer.

OOTACAMUND,
6th December 1879.

SYDNEY EXHIBITION.

Dated Elizabeth-street, No. 717, Sydney N.S. Wales, *viâ* Galle, the 23rd December 1879.

From—Major M. Clementi, Bengal Staff Crops,

To—The Offg. Secretary to the Government of India, Home, Revenue, and Agriculture Department.

I HAVE the honor to acknowledge the receipt of your letter marginally noted, with copy of telegram of the 17th October.

No. 367, dated Simla, the 24th October 1879.

2. In the face of considerable difficulties which I need not now more refer to, I have managed to display all the exhibits with the exception of one large carpet.

3. I have been careful in the matter of expenditure, which has been less than I estimated. As requested by you, I will furnish a detailed account of the expenditure at the close of the Exhibition.

4. I gather from the newspapers that the Government of India purpose participating in the forthcoming Melbourne Exhibition. Melbourne, I may say, is very far in advance of Sydney in civilization, and I would therefore suggest that the art manufactures for that Exhibition should be selected with care.

5. I would suggest for selection the following :—

Castor and other oils; Indian pottery; a small quantity of Bombay blackwood furniture and sandalwood goods; Lucknow, Sind, and Cashmere silverware, *surahis*, and so on; *chuddars*; shawls; *choghas*; *malida*, and similar cloths, silks, muslins, cottons, prints, chikan works, carpets; a small and light Swiss cottage tent complete, with iron pegs, and a small sleeping pal; native jewellery; Benares, Moradabad, and Gujrat metal wares; Agra mosaic and inlaid stone-work; Jaipur figures in marble; photographs; papier-mache; ivory work; medicinal barks and roots; dyes; tea; coffee; spices; tobacco; rice; sugar; shell-lac, rough and prepared; gunny cloth and bags and woolpacks.

6. It would be a saving of expense, labour and material being so much dearer in these colonies than in India, if the show-cases could be sent down with the exhibits; they should be of teak, or some other strong wood, and the larger ones should be packed in pieces, the glazing and polishing being left to be done at Melbourne.

7. The show-cases sent down from Madras are not suitable for the protection of the exhibits from persons, or from the atmosphere and dust; and as they were sent glazed, there was loss from breakage. Moreover, the style of the cases do not admit of good arrangement, or for the most advantageous display of the exhibits.

8. Some of the teas from the Bengal side were sent down in stopper bottles; but the packing was so bad, that a large number of the bottles were on arrival, found to be broken. The treatment packages receive in transit to this, is so rough as to necessitate strong cases and the most careful packing. In some instances the bottles were smashed to atoms I had better mention also that the indigo from Madras came through the wrappers, and discoloured some of the grain exhibits; and some of the coffee bags (which are not of very strong material) burst, and the contents got mixed.

9. The labels for the exhibits from either Presidency were not very securely fastened on, and many came off.

10. I think that stopper bottles are as good and inexpensive a way as there is for exhibiting teas, coffee, spices, grain, manufactured tobacco, oils, sugar, dyes, roots, &c., &c.; for cinchona barks tobacco leaf, and other long exhibits, bottles are unsuitable. The labels might be placed at the bottom part of the bottle, and be of such size as to leave the contents of the upper part open to view. In addition to other descriptive matter, the labels had better give the prices. This is the more important, as prices are not allowed in the official catalogue. This suggestion as to marking the prices applies to all exhibits, and not only to those in bottle.

11. The bottles might be packed in strongly made cases, with the tops screwed, not nailed down, each bottle being in a seperate partition and these cases should not be too large. This method of packing may be dearer than that commonly adopted, but it will I venture to say prove to be cheaper in the end.

12. There would seem to be no occasion to send more than fair samples, and a 40 ounce bottle will as a rule hold quite sufficient tea, both for exhibition and for tasting. If it be considered advisable to send larger quantities, then the bulk might be packed separately; but the samples in bottle should I think, be sent for to open tea and keep it exposed for any time is to cause it to deteriorate in favour and exposure to the air is not necessary until the time for judging. Large and nicely printed cards givings names and addresses of respective exhibitors, and their local agents, together with any description necessary or advisable (descriptive matter not being permitted in the official catalogue), might well accompany the different collections of exhibits.

13. I found that the catalogue sent from Madras was not in accord with the official classification and rules promulgated by the Sydney Commission. But, as I had to make a general catalogue for the entire Indian section, this did not much matter; and I distributed the Madras catalogue as an unofficial one. Copies of the Indian catalogue will reach you, I trust by the Torres Straits mail leaving this on the 27th instant. The descriptive and unofficial part preceding the catalogue, headed "Statistics," I compiled from the Madras catalogue and other sources. Had there been time, I should have reffered to your department for this part, and I would suggest that the statistical and descriptive portion of the Melbourne catalogue be supplied from India.

14. The prices marked on the metal wares and on the shawls, do not tally with those given in the lists I received from your department. I am disposing of those articles at the prices marked on them, although these are somewhat lower than the prices given in the list.

15. May I ask you to do me the favour to correct the statement officially made in India that I am a retired officer? I have the honour to be, sir, your most obedient servant.

(Sd.) M. CLEMENTI, MAJOR,
Bengal Staff Corps.

No. 2 of 1880.

GOVERNMENT EXPERIMENTAL FARM, KHANDESH.

BHADGAON, 10TH JANUARY 1880.

Progress Report of the Superintendent of the Khândesh Farm for the half-year ending 30th December 1879.

THE monsoon although measuring only 34 inches in all, dragged itself out to an unusual length, and being, especially towards the end, accompanied by extreme cold, country-people generally suffered severely from a peculiar fever called *Hewa*, the symptoms of which are not unlike those of ordinary *Dengue*. At times as many as half the entire rural population were laid up with this fever, and field work, of course suffered accordingly. Especially was this the case during the cotton weeding season, and many fields remained unattended to. In spite of this, however, the crop is everywhere turning out remarkably well. Statistics of the farm crops have not yet been obtained, but, with the exception perhaps of jowari, they will certainly compare favourably with the best of any previous year.

New Implements.

2. The new cotton plough and scraper mentioned in last report, have fully maintained their reputation during the season, and are now being much asked for by the cultivators.

Selected Cotton Seed.

3. Great attention has this year been paid to the selection of good seed for distribution, and as many large growers who were last year supplied with pure seed have also kept their stock for sale at sowing season, the demands on the farm store will this year probably be lighter.

Malachra Capitata.

4. This fibre plant (Ran Bhendi) a sowing of which was made under Government Resolution No. 1983 of 15th April 1879, has done very badly, not more than five per cent. of the seeds germinated, this is a very common result of any first attempt to put a wild plant—under the ordinary conditions of cultivation. In such cases the seeds usually come up the second year.

5. Although the sowing of the plant is so far unsatisfactory, it is otherwise with the experiment as a whole, a sufficient quantity has been found growing spontaneously in the fields to produce if not a ton of fibre, at least as much as will afford a thoroughly practical test as to the suitability of the article for spinning and weaving.

Cow Tree (Brosimum Galactodurdron.)

6. Several new trees have lately been introduced, the principal of which is the cow tree of South America, which is said to yield abundance of milk (from incisions made in the bark) equal in quantity to that of the cow. It is therefore a tree of immense

importance, and its successful introduction into India would be a valuable achievement.

7. So far, the seeds planted here have not germinated, neither however, have they rotted, so that there is still ground for hope that they may not have lost their vitality.

Cane Mills.

8. The only new machine received on the farm during the half-year, is a sugarcane crushing mill, the invention it would appear of Messrs. Thomson and Mylne of Beheea. The advantages claimed for this invention over the native mills of that locality are :—

1st.—Economy in working.
2nd.—Cheapness of up-keep.
3rd.—Portability.

For very small canes the machine may be all that it is represented to be, but it is evidently far too fragile to crush the large ligneous canes commonly grown in this part of the country. A series of carefully calculated trials will be conducted and the results duly reported.

9. The five heavy iron mills sent out by Mc.Onie, and others, are by far the best ever made. Of the five belonging to the farm, only one remains to crush the cane crop, the others are all out in the district on hire.

Silk Factory.

10. During the past rains, attention has been mainly directed to the rearing of the tusser worm in the open air. Two crops were obtained, the first was eminently successful, the second, owing to the protracted cold rains mentioned in para. 1 was a partial failure. Plantations of different kinds of food plants are now being made, when it is expected that more uniform results will be secured.

11. The Mulberry silk experiment continues to show a fair amount of success, the quality of the silk has not so far been critically examined, but its value will now be satisfactorily determined, as a bale of the raw material has been sent to Major Coussmaker who will dispose of it in the open market.

Stud Horses.

12. A few magnificent Arab pony stallions have just been added to the Stock Department, which is now becoming the most important section of the farm, nothing but the very best results can be expected from this new scheme. The Khandesh ponies sent forward for baggage purposes have proved themselves marvels of endurance, wanting only in symetry. This latter defect will readily be remedied by the Arab sires, specially seeing that so few native ponies are left to interfere with the progress of improvement.

13. The ponies of the Scotch Hebredies own their faultless forms and wonderful constitutions to Scandanavian blood introduced by the *Norwegians* and *Danes* many centuries ago. Similarly a few superior stallions which escaped from one of the vessels of the *Armada* wrecked of the coast Galloway, gave rise to a breed of horses (galloways) which even to this day are worth 25 per cent. more in the market (size for size) than any other breeds of horse.

There seems no reason why the scheme now being started for the improvement of our long neglected native ponies should not be equally far reaching in its results.

A. STORMONT,
Superintendent.

NAGPUR FARM—HALF-YEAR ENDING 31st DECEMBER 1879.

Extracts.

I HAVE the honor to submit the following report on the working of the Nagpur Farm during the past half-year.

From the marginal statement it will be seen that the total rainfall registered during the prevalence of the south-west monsoon was 45 inches ; this total includes 7 inches of the heavy fall of 31st May and 1st June, and as there has been no fall registered since the 9th October, the rainy season may be said to have lasted 131 days.

	Inches.
1—15th June	7·32

Jowari.

Jowari was sown as a primary crop in five fields, and as a complementary crop in the cotton and thur. The fields chosen were Nos 1, 5, 8, 16, and 40, of which No. 8 alone is completely black soil, the others being partly black only, "murand" cropping up occasionally, especially it Nos. 16 and 40. With the exception of No. 1, these fields are all situated on a more or less inclined slope, and from their position, Nos. 5, 16, and 40 are more than usually cut up with water-courses. Manure had been applied to No. 1 field in the hot weather of 1875 in the form of town sweepings and also to No. 5 in 1876, but the other fields have not been manured by us.

The preparation of the soil was restricted to "bakhuring" before sowing, but in the case of Nos. 1 and 16 alternate strips were ploughed as an experiment. Sowing was carried out at the end of June and the beginning of July, and germination was complete.

The heavy rain which fell continuously damaged the crop in the low lands of the black soil as well as on the poorer mixed soils, where the constant moisture caused some plants to be washed away, others to rot, and the rest to remain stunted and weak.

In the higher lands and on the richer level soils the crops withstood the impoverishing effect of the heavy rain, although everywhere by the month of August jowari presented an unfavourable appearance. Outside the farm it may be noted that jowari on the whole remained healthy ; but in the immediate vicinity of Nagpur, on the western side of the city, this crop is generally grown on stony ground as a field crop or on very rich soils as a garden crop. In the former case an evenly distributed heavy monsoon is favourable, and tends to induce the production of a uniformly good stalk wherever the ground is only fairly drained ; on the other hand breaks of ordinary duration would, in many cases, prove fatal to jowari grown under such circumstances.

Our cultivation of jowari on the farm may be more rationally compared with the garden growth, in which case, as with us, the production of grain is the great *desideratum*. The appearance of the garden grown jowari is familiar, and its more prominent feature of excessively tall growth was very marked during the past season, yet when the time of flowering and fruiting came, the "bhoottas" where only small and unhealthy, as if the vigour of the plant had been absorbed in the production of the stalk. Nor was the consequent diminution in the grain outturn compensated by any superiority in the fodder the crop gave, on the contrary, jowari under conditions whereby its stalks are thick and long is not so paying, as far as fodder is concerned, as when the crop remains short and the stems thin, which is the case generally on the poorer soils with the ordinary system of cultivation.

This unfavourable result of garden-grown jowari, *viz.*, the production of small heads on long pithy stems, we avoided at the farm by our having sown our crops later than the garden growers, and the dwarfing of the stalks was no doubt assisted by the unceasing wet weather. As yet the crop is standing, so nothing certain can be said regarding the yield ; but it can safely be asserted that the grain crop in Nos. 1 and 5 fields will be a more than ordinary one, and far superior to the others, although, in the former instances, as well as in No. 16, 3, 4, and 5lb. of seed per acre were sown as compared with 9lb., and more per acre in others. The quantity of manure in Nos. 1 and 2 is very slight ; but yet I am convinced that in both cases the crop being superior is due to the land having been manured as well as to thinner sowing and careful constant weeding.

It was originally intended that the year's experiments with the jowari crop should be conducted with a view to determine the effects of ploughing on the growth and outturn and the result of thinner sowing. The experience gained by the native Superintendent and the farm servants is completely local as regards the crops, and that no doubt accounts for our having hitherto sown so much jowari seed per acre by following, on richer soils with heavy cultivation the measures adopted by the surrounding jowari cultivators in their efforts to grow fodder on the poorer soils with but slight cultivation. The outturn in No. 1 field will I believe show that rich soil well cultivated and thinly sown, yields a good commercial return in its grain value for the extra cost of cultivation, whilst, as already noted, the fact of our ploughed strips remaining green whilst our lightly cultivated bands of soil were withered by an early break, points to the singal advantage to be derived from a seed bed deeper than that usually selected by native cultivators.

In carrying out our experimental growth of jowari with the objects already recorded, we were hampered by some difficulties. The impossibility of getting a suitable large area of uniform soil reduces the value of the experiments, by our having to carry them out on small plots. Otherwise by including various soils in our experimental plots, we introduce elements of uncertainty into the figures on which our results are based. A second difficulty arose during the past season from our sowers being cultivators who from their youth up had been accustomed to sow jowari thickly, and to feed the drilling machines at a certain pace, and who find it difficult to stay their hand and dispense a lesser amount of seed regularly.

On these accounts our original plan of sowing alternate bands with fixed amounts of seed per acre, in fields ploughed crosswise in alternate strips, was frustrated, and the crop if successful will only prove that thin sowing give good results, and that a deep seed bed is advantageous under certain climatic conditions ; but in order to set down with any certainty the amount of seed per acre which will give the best return, a continued course of experiments must be undertaken.

In concluding this notice of the jowari crop, I would refer to the very superior fruit heads yielded by stalks in the thur and cotton bushes, and one

the fact that a vigorous growth of jowari plants from 10 to 15 feet apart seems in no way to interfere with a shrub under growth of either cotton or thur; whilst, on the other hand the past season has directly shown that whether from any protection afforded by the surrounding growth or assisted by other kindred conditions, a complementary crop of jowari so interdistanced will prove highly remunerative.

I would also state that, by desire, the subject of jowari cultivation has been especially gone into, as its former growth at the farm had left much information ungained or unrecorded.

Cotton. Since the establishment of the farm, repeated experiments have proved that cotton grown under an expensive and thorough system of cultivation, will amply repay the outlay, while in 1878-79 an attempt was made to put into practice the experience so gained. The monsoon of that year destroyed the crop at a very early stage of its growth; but during the past season we have succeeded in getting a large well cultivated area stocked with cotton plants of a superior variety, and hopes of a success are entertained.

The plants came up evenly and strong, and when the heavy rains came on they withstood the moisture. Weeding was a difficulty, but no visible harm was done from our not being able to carry it out at the proper season. The fields chosen are uniform in level and soil for a considerable area, and only on the lower fringe was the ground so swampy during the monsoon as to materially prevent the plants from bushing out. Picking commenced in the middle of October, and up to date the outturn from about 25 acres has been 500lb. of clean cotton, representing about 2,000lb. of picked bolls, which, with about 200lb. of soiled cotton, makes up an average of 88lb. of unginned cotton, or 22lb. of clean cotton to the acre. This may be looked upon as the result of the first picking, and a much larger outturn is expected from each of the succeeding ones. Our actual yield would no doubt have been considerably greater had not the final rains of the monsoon induced worm in the first formed bolls, and the cloudy weather at the close of October affected the whole of the flowers and fruit still on the bushes. The bolls now forming are small, partly owing to the last mentioned cause, which interfered with the development of the flower, but the chief reason is undoubtedly the unusually early and severe cold weather we experienced in the months of November and December. Now that the temperature is more even, it is expected that our yield will increase, and the irrigation now about to be carried out will also have a beneficial effect.

It is worthy of remark that the greater portion of the cotton as yet plucked is the fruit of plants which from various causes never branched much and flowered precociously; while the large mass of the crop was still growing and spreading. This early flowering of a portion of the cotton has been taken advantage of to lay in a stock of the seed in order to try and perpetuate as an early cropper.

Until now the proportion by weight of seed to clean cotton has remained fairly constant at 3 to 1, but it is probable that this proportion will decrease when the crop is in full fruit.

Cotton was also grown on some 5 acres in another section of the farm where the soil was of a much lighter description. The preparatory cultivation was not heavy, and the plants were completely checked by the wet; at the same time the unsuitability of the soil was proved by their never recovering when the lands dried.

There was also an attempt made to grow the later sown variety of Jheri cotton from seed imported from the Chanda district, but it did not germinate freely, and the young plants that did appear made no progress, and many died down. Seeing that it was impossible to get any crop, and that the land was in good order, it was ultimately sown with wheat, which has so far succeed admirably. In future experiments with Jheri cotton at the farm, I would advocate that its cultivation be restricted to small areas, until our knowledge of the particular requirements of the crop is more extended than at present.

The Bhamieh cotton plants are now of two years' growth, and this season a small quantity of good cotton has been yielded by them, though in point of colour our Indian home grown varieties are superior. The plants are tall and flower well, but few of the fruit come to perfection, and even they are generally perforated by worms. This variety of cotton has a remarkable tendency to throw up suckers, which perhaps may account for the weakness of the parent stem and fruit.

Rice. The Chimur variety was again experimented with, and with some amount of success. Transplants from a large bed of seedlings were put out, and in parts the outturn will be fair, but nothing equal to what would be the return on similar soils from locally grown varieties. The plants grew well at first, but afterwards did not "tiller" out. On the Thelinkheri estate near Nagpur, the same inability to spread out on the part of this variety was very marked; especially as other kinds of paddy grown under similar conditions of soil and treatment succeeded admirably. At the same time it should be noted that a small plot on the farm which in the previous monsoon had been under Chimur rice, gave a small crop of plants self-grown from seed which had remained the whole year in the ground. The produce of these plants was considerable for their number, and the plants themselves were tall and tillered out wonderfully. From this I am inclined to consider that our rice fields are of too stiff a soil for this variety and that the lands would require considerable quantities of vegetable manure to be added to them to cultivate it successfully.

Turmeric, ginger. Experiments were also carried out with turmeric and ginger, which in the previous year had been tried but found unable to cope with a very heavy monsoon. This year they have done better, but at no time have they been luxuriant. It remains to be seen what their yield will be before determining on their cultivation being a success or not.

Thil. Thil sowing was carried on at the proper season, but it was found that the ground was too wet for the seed to germinate well, and it had to be done over again. Where the soil was drier a fair crop came up, but its growth is not luxuriant, and I would not suggest its cultivation being attempted commercially.

Gram. Gram has been extensively sown wherever suitable fallow land was avilable and time permitted. Portions of the jowari and thur fields where the rains had swamped the original crops were put under gram, which has come up well. The outturn is expected to be a good one.

Linseed. Linseed has been sown over an area of 83 acres. The seed came up fairly, but in parts the ground was so wet and sticky, that no amount of cultivation could get it into order in time for the crop. In one field where germination was markedly incomplete on this account gram, was afterwards sown with success. In other fields the varied nature of the soil has caused an uneven crop. Wherever the "murund" outcrops, the plants are fewer and less strong, and the thinness of the crop on these spots is owing to the ground having become too dry before the blacker soils were sufficiently dry to sow the seed in. This want of uniformity in the soil is the chief consideration, owing to which it is so difficult to obtain a regular *rabi* growth over any area at the farm.

Wheat has been sown in 7 fields over an aggregate area of 44 acres. The varieties selected for cultivation were the "Haura," which has been so successively grown for some years past; the "Pissi," a soft white of superior quality from the ghâts in the Seoni district, and "Jelalia" from the Nerbudda Valley.

Unfortunately the Commissioner's instructions regarding the extensive cultivation of the soft white wheats, which are so highly valued in the home market, were received after our season's sowings had been completed, and an investigation of the conditions of the growth of this class of wheat is therefore reserved for the next year. I would mention that hitherto our chief success in wheats has been with the hard white varieties, which although they may not find favour with the English miller, yet appear to be preferred by the wheat-eating population of this part of India.

From the shortness of the time during which wheat lands must be prepared and sown, great difficulty is experienced in getting any considerable area of ground into good order with the ordinary strength of stock on the farm, and although this year every other work was set aside for the furtherance of this object, yet even assisted by the loan of several head of cattle from the Mahraj Bagh, it was found impossible to get all the seed in by the time the seed bed remained in order to receive it. This is the sole cause of a partial failure to germinate of the wheat in No. 89.

The seed in other fields came up well, but thinly as compared with the number of plants observable in an ordinary ryot's field. This is no doubt owing to our seed bed being deeper and the germination of the seed slower and more uncertain; but the advantages of our system of cultivation are invariably apparent later on in the age of the crop when each plant "tillers" out.

In continuation of an experiment with English wheat carried out by my predecessor, an area of three acres was thoroughly prepared and manured and put under first-rate fresh seed carefully consigned to me by an English farmer. The varieties he had selected were the "White Foster," "Short Essex," and "Buff Talavera, the last named being a spring wheat. The seed arrived in first-rate order, but the "White Foster" was much weevil-eaten, and both it and the "Short Essex" failed to germinate. The "Buff Talavera" partially came up, and the few plants obtained are strong and healthy.

After the present season, I propose to discontinue experimenting with foreign varities, as our home grown wheats are quite as good, if not better, and as far as English seed is concerned, it is a matter for consideration, whether it is possible to assimilate the conditions of its growth in England to those it must be subjected to in this tropical latitude.

In connection with the cultivation of wheat on the farm during the present season, I would observer that the ploughing of the lands in preparation for the crop was carried out during the fine weather in September, by means of ploughs made on the model of the American one received from Cawnpur.

In the previous year, owing to the impossibility of getting the work done in time by the ordinary English ploughs, or by the improved native ploughs, the lands were simply "bakhured," whereas in the present season, as I have said, the whole area was really ploughed up.

Having now passed in review the various important crops, the cultivation of which has been undertaken at the farm during the present season, I would state that the wishes of the Chief Commissioner imbodied in your review of the last year's report concerning the exact separation of the charges attending the various works have been rigidly carried out; and in conclusion I trust that the superintendent, in submitting the next half-yearly report may be in a position to record some success as the result of the work that is being carried out during the present season.

E. D. M. HOOPER,
Superintendent.

SELECTIONS.

HOW TO SAVE AND KEEP MANURE.

WHEN properly littered one cow or ox would make a ton of manure every month, if the liquid as well as the solid portion is saved. Ten heads would thus make 120 tons, or sixty-two horse wagon loads in a year. A pair of horses will make as much manure as one cow, or 12 tons in the year. A hundred sheep, if yarded every night and well littered, will make 100 tons of manure in the year, and ten pigs will work up a wagon load in a month if supplied with sufficient coarse material. The stock of a 100 acre farm—which should consist of at least ten cows, ten head of steers, heifers and calves, a pair of horses, 100 sheep and ten pigs—would then make in the aggregate 315 tons of manure every year, or sufficient to give 12 tons per acre every fourth year. If this were well cared for, it would be, in effect, equal to double the quantity of ordinary manure; and if a plenty of swamp muck could be procured at least 600 tons of the best manure could be made upon a 100-acre farm. If this were the rule instead of a rare exception, or only a possibility, what a change would appear upon the face of the country, and what an addition would be made to the wealth of the nation!—*American Agriculturist.*

AGRICULTURAL REFORM IN INDIA.

THE *Asian*.—We cannot agree with Mr. Hume that 'the only hope for India' lies in the chance of such questions being better understood and discussed in England, for late events have shown that a discussion of Indian matters of England only means their being made use of in party politics. Agricultural reforms and improvements are best discussed, and can only be effectually carried out in the country to which they are to be applied. The result of such a discussion in England would probably be an invasion of travellers for the sale of complicated agricultural machinery quite unfitted either to the means of the rayats or the crops grown. If improvement is to be made it must be by the establishment of farms under competent men like Mr. Robertson in the Madras Presidency, and by a practical man like Mr. Harman, also employed in that much too derided presidency, travelling round the country and showing the rayats what can be done with an improved plough, the cost of which is not above their means. This brings matters home to them better than the longest and most scientific reports ever written by a Director of Argiculture in the North-West Provinces or anywhere else. But still we would not do away with such an office. There should be some recognized official to encourage improvement in agriculture in every province of the Empire, and not the least good work of the present Lieutenant-Governor of the North-Western Provinces is likely to be his having persuaded the Taluqdar of Oudh to form an agricultural association for the very purposes to which Mr. Hume's efforts were directed. Let other Lieutenant-Governors and Chief Commissioners profit by so good an example.

MR. MARTIN'S PLOUGH.

WE have received the following lettter regarding the experiment of a new agricultural plough, to which we referred last week:—

The current number of the *Indian Agriculturist* briefly notices, in an editorial note, the results of a trial of a new plough invented by Mr. William Martin, indigo planter and zemindar, Mynpoore, North-Western Provinces. The trial in question was held in some of the fields at Bally in the presence of the editor of the *Agriculturist* and a large number of cultivators who witnessed it with great interest. There were two of Mr. Martin's ploughs and two others made at the Cawnpore Model Farm under the superintendence of the Department of Agriculture and Commerce, North-Western Provinces. There was a large gathering of the cultivators, who brought their own bullocks to yoke to these new ploughs, and the result was that they were extremely pleased with Mr. Martin's plough and thoroughly convinced of its superiority over the common country plough. In fact, as the *Agriculturist* says, "they were in perfect raptures and loud in praise of it."

They found they could use it without the slightest difficulty, and it was so light that the bullocks actually ran away with it. The common country plough must be dragged at least a dozen times over the ground before it could pulverise the earth, whereas Mr. Martin's plough attains that object at once by cutting an octagonal furrow to any depth desirable and turns the soil upside down. The ryots readily recognized the advantages of Mr. Martin's plough, which secured deeper ploughing and at the same time economized labor. And in their anxiety to adopt the new implement immediately, they wanted to keep the plough with them. The merits of the plough will be obvious to all, who take the trouble of testing or seeing it. The plough made at the Cawnpore Model Farm was also tested, but the peasants gave much preference to Mr. Martin's plough for the following reasons, that they found the former too heavy for the ordinary draught cattle, and secondly two men wen were required to work it—one to hold the stilts and the other to drive the bullocks. Public interests imperatively demand that Mr. Martin's plough should be made known in this country, and I have no manner of doubt that all cultivators who see it working will be only too ready to adopt it. The plough is now lying at the office of the *Indian Ariculturist*, where it can be seen by all persons interested in agricultural reform in this country.—*Hindoo Patriot.*

PHYLLOXERA VASTATRIX.

THE ravages of phylloxera, the most destructive of all the numerous enemies of the vine, were first observed in Europe in 1865, in the department of Gard, France; but it was only in 1868 that M. Planchon, Professor of Sciences at Mont-Pellier, discovered the insect and named it phylloxera vastatrix; the word phylloxera intimating the drying and withering of the vine leaf. It appears under two forms, the *winged* and the *wingless*. When largely magnified, the wingless insect has the appearance of a tortoise, only it has rather long legs and a trunk; the back is divided into squares, from which project little excrescences; the head is slightly bent under the body, and the brown eyes have numerous facets. The phylloxera is an American insect, and appears, as already said, in two forms. The first (winged) forms galls on leaves, and is met with in all parts of America on the leaves of wild vine; the second seeks the roots, and is the only dangerous one. Both kinds are of a waxen yellow tint, but otherwise look like the common plant-louse, or aphis, only they are very much smaller—hardly the size of a very small pin's head. As ordinarily found, sucking the rootlets of vines, the insect is wingless, and all are females; or, at least, egg-layers; for there are no males for three or four generations, during which each of the insects may lay from 200 to 400 eggs apiece, which hatch in about ten days. About the fourth generation a winged form makes its appearance, whose wings are so large in proportion to their bodies that they have little control over them; but when they rise in the air they are carried wherever the wind may chance to take them. Those lay only three or four eggs each, which produce two kinds of phylloxera, large and small, the former being females and the latter males. This generation has no digestive organs, being destined exclusively for reproduction. The female lays but one solitary egg, which is especially tenacious of life, being destined to hibernate. From this egg is hatched, on the return of spring, the ordinary root-louse, whose vigor is thus annually renewed. It is the winged form, then, which renders possible the rapid spread already also, that its destruction would speedily put an end to the propagation of the species. But Nature has provided against this contingency, for in time of need some of the common egg-layers undertake to lay the large solitary egg which hibernates; and moreover in a mild climate some of the millions of the common eggs, and a few egg-layers, also survive. These eggs can be destroyed by from twenty-eight to forty day's submergence, which can only be done in winter without injury to the vines.

This, so far, is the "only absolute remedy found," except in very sandy soils, because it is too weak to crawl from one place to another, the grains of sand obstructing its progress. In adobe soils it crawls along the cracks. No one in this state, nor, I venture to say, anywhere is better informed on phylloxera, or has better or more extensive appliances for demonstrating the life-history of this pest than Professor E. W. Hilgard, of our State University, and it is to his studies I mainly owe the substance of this short essay.

In France its ravages have been such that, as much as four years ago vineyards were unsaleable, no one would venture to spend any money in such property. As to California, it is fast sweeping the vineyards of Sonoma, and unless some desperate and ultimate measures be taken very soon, nothing can keep it from spreading through the adjacent valleys; and every day renders its extermination more and more difficult. How far submersion may be practicable in the Sonoma Valley, can only be decided by a survey of the creeks. But as the only absolute cure, the destruction of the "large egg," it should be had recourse to if possible, and the adjacent country compelled to contribute to the expense. The system of submersion was originated in France by a M. Faucon, whose vineyard of forty acres is situate close to the Canal de Durance. The submersion is made in October, and continued for forty days. Here are his results: The year 1867, the one preceding the invasion of the pest, the yield was 2,775 galls.; in 1868, first year of invasion, 120; 1869, second year, 105 gallons only; 1870, first year of submersion, 860 galls., 1871, second year of submersion, 1,350, without manure; third year, with manure, 2,547 galls; fourth year, with manure, 2,175 galls.; fifth year, with manure, 3,750 galls; sixth year, with manure, 7,800 galls. So a vineyard that, in 1862, yielded ed only 105 gallons in all, in six years was brought back to yield more than twice as many gallons as it did before the invasion of phylloxera.

The reports from France just to hand say that the yield this year will hardly reach one-third of ordinary years before the invasion.—*Ceylon Times.*

THE INDIA-RUBBER TREE.

(From the South American Journal.)

A CORRESPONDENT of an American paper, writing from the Brazils gives the following interesting particulars of the process of tapping the India-rubber or caoutchouc tree, and of manufacturing the gum into shoes and other things:—

The caoutchouc tree grows, in general, to the height of forty or fifty feet without branches; then branching, runs up fifteen feet higher

The leaf is about six inches long, thin, and shaped like that of a peach tree. The trees show their working by the number of knots, or bunches made by tapping; and a singular fact is that, like a cow, when most tapped they give most milk or sap. As the time of operating is early day, before sunrise we were at hand. The blacks are first sent through the forest armed with a quantity of soft clay and a small pickaxe. On coming to one of the trees, a portion of the soft clay is formed into a cup, and stuck to the trunk. The black then striking his pick over the cup, the sap oozes out slowly. A tree gives daily about a gill. The tapper continues in this way tapping about fifty trees, when he returns and with a jar, passing over the same ground, empties his cups. So by seven o'clock the blacks came in with their jars ready for working. The sap at this stage resembles milk in appearances, and somewhat in taste. It is also frequently drunk with perfect safety. If now left standing it will curdle like milk, disengaging a watery substance like whey.

Shoemakers now arrange themselves to form the gums. Seated in the shade, with a large pan of milk on one side, and on the other a flagon, in which is burned a nut peculiar to this country, emitting a dense smoke the operator having his last, or form, held by a long stick or handle, previously besmeared with soft clay (in order to slip off the shoe when finished), holds it over the pan, and pouring on the milk until it is covered, sets the coating in the smoke, then giving it a second coating repeats the smoking, and so on with a third and fourth, until the shoe is of the required thickness, averaging from six to twelve coats. When finished, the shoes on the forms are placed in the sun the remainder of the day to dry.

Next day, if required, they may be figured, being so soft that any impression will be indelibly received. The natives are very dexterous at this work. With a quill and a sharp-pointed stick they will produce finely lined leaves and flowers, such as you may have seen on the shoes in an incredibly short space of time.

After remaining on the forms two or three days, the shoes are cut open on the top allowing the last to slip out. They are then tied together and slung on poles, ready for the market. There pedlars and Jews trade for them with the country people, and in lots of one thousand or more they are again sold to the merchants, who have them stuffed with straw, and packed in boxes to export, in which state they are received in the United States. In the same manner any shape may be manufactured. Thus toys are made over clay forms. After drying, the clay is broken and extracted. Bottles, &c., in the same way According as the gum grows older, it becomes darker in colour and more tough. The number of caoutchouc trees in the province is countless. In some parts whole forests of them exist, and they are frequently cut down for firewood. Although the trees exist in Mexico and the East Indies, there appears to be no importation into the United States from these places. The reason, I suppose, must be the want of that prolificness found in them here.

The caoutchouc tree may be worked all the year round; but generally in the wet season they have rest owing to the flooded state of the woods; and the milk being watery, requires more to manufacture the same article than in the dry season.

JUTE IN BOMBAY.

WITH reference to our remarks last week pointing out what gross neglect there will be on somebody's part if the hemp and jute manufacture is not preserved to Bombay, we have the following from a correspondent:—

As regards the Jute Mills, the property has been advertised for sale, and I do not think it will fetch even two lakhs of rupees. It can now be worked at a profit; and if shareholders could raise among themselves two lakhs of rupees (100 per share would produce that sum), the claims of the creditors could be satisfied, I believe, for ten or eight annas per rupee, which would absorb about Rs. 1,75,000, leaving Rs. 25,000 for working capital. Why should not, as you say, some of our young men get up a small company to work the Jute Mills as they stand? The machinery is fairly good—very good in some respects; and after this favourable monsoon, hemp should be available all up and down the coast of Western India, while the demand both for twine and "hessians" will be very active.—*Bombay Review.*

ARTESIAN WELLS IN PONDICHERRY.

IN the last number of the *Moniteur Officiel* of Pondicherry there is a letter from M. Poulain, Civil Engineer. It is interesting in many ways, and furnishes much information that will prove useful to those who are engaged in agricultural pursuits and who may be considering the chances of striking water through the means of Artesian wells. It appears that Pondicherry is bounded on the north and the west by a geological formation known in science under the name of tertiary. This is nothing more or less than the formation which crops up at the Red Hills. It consists of laterite. To the south of this formation flows the Ponear in a valley composed of *débris* (*detritus*) of the laterite range. Every shower of rain washes down from the Red Hills, the particles that have been disintegrated by the action of the sun and air, and carries into the valley below a mass of mud which consolidates and in the course of years accumulates into an alluvial formation. The Artesian wells which have proved a success lie in the alluvial formation, and they tap water at this point where they meet the tertiary formation. The thickness of the aluvial deposit varies and is found to be over one hundred and sixty-four metres, equivalent to about five hundred and thirty-three feet. At this depth water has been tapped, and the well promises to turn out a success. Is it not discreditable that the Government of Madras should stand idle while this important work of boring Artesian wells is being steadily prosecuted by the Pondicherry Government? It reflects great discredit upon the Public Works Department whose inefficiency is thereby conspicuously brought to light. Colonel Mullins has criticised the good work done in Pondicherry, and Mr. King of the Geological Survey, doubts whether the wells at Pondicherry are really Artesian wells. But facts are proverbially stubborn things and, notwithstanding anything that Colonel Mullins and Mr. King may say, these Artesian wells are very useful in Pondicherry. There are thousands of localities in British India situated under conditions similar to those in Pondicherry—localities in which Artesian wells might be sunk with advantage. Proprietors of land are anxious to have something done in this way to improve their lands, and they cannot but consider the authorities who are responsible, open to the charge of neglecting a duty which will redound to their credit and be of advantage to agriculturists.—*Madras Standard.*

SIR ROBERT CHRISTISON.

THE great Scoth chemist has made some curious observations on the effects of a cold, wet season in diminishing the normal growth of trees. He makes out, on careful measurements, that comparing 1879 with 1878, eleven deciduous trees—not oaks—made on an average 41 per cent. less growth in last year than in the year before. Of 17 pine trees, the average deficiency was 20 per cent.; and of seven oaks, the deficiency was 10 per cent.; so that heat appears to have more to do with the making even of wood than moisture has. It is strange that the growth of the oak, which drops its leaves, seems less dependent on heat than that of the pine, which we usually associate with very cold regions; but perhaps, it need not be the tree which is most stunted by cold, which is most easily killed by it. The arrest of growth may sometimes be a safeguard against vital injury.

MINING IN NEW CALEDONIA.

A FRENCH company has been formed, with a nominal capital of £1,920,000, for working the nickel and cobalt mines of Bel-Air, in New Caledonia. The copper mine of Ballade produces nearly a thousand tons of ore a month, which is all forwarded to Newcastle (New South Wales). The gold mine of Galatino is being worked vigorously, and it is said to be of great richness. A new branch of mining industry has lately been opened up in the Chesterfield guano deposits, which are being worked by experienced men, and are said to equal in wealth any similar deposits in the southern hemisphere. Three hundred tons of chromate of iron were recently despatched to Brodeaux on board the *Saint Marc* as an experiment, and it is expected that a considerable trade may grow up in this product, as it is believed to contain an unusually large percentage of oxide of chrome.

THE JUNCTION CANAL AND WELL WATER.

A QUESTION some time ago arose as to the effect of the Junction Canal on the well water in the Mylapore district. In a letter to the President of the Committee appointed under G. O. No. 4544, dated 27th November 1878, Dr. Cornish, Sanitary Commissioner for Madras, stated that to test the question whether the salt-water of the canal would affect the neighbouring wells, specimens of water would be periodically examined. Three wells were chosen for observation; one distant, 100 yards from the canal, another 150 yard distant, and one 25 yards, and all to the eastward of the canal. Specimens of water were selected in December 1878, and again in December 1879, as near as possible on the same date, and the result of the Chemical Examiner's analysis shewed that wells distant 100 and 150 yards, respectively ly, have become slightly more saline, the chorides increasing from 0·292 grams, per litre to 0·345, and from 0·331 to 0·404, but in the well nearest to the canal, and distant only 25 yards, the amount of sodium chloride has *decreased* from grams, 0·169 per litre in December 1878 to 0·071 in 1879. The deduction Dr. Cornish draws from the facts is, that there is no present evidence to show that the canal has increased the saltness of the neighbouring wells. The slight increase noted in wells 150 and 100 yards distant may be due to the temporary disuse of them for irrigation purposes. The observations are to be repeated next year.—*Madras Times.*

THE NEGLECT OF POULTRY BREEDING.

TWO million and half sterling per annum is a large sum to send out of the kingdom for eggs, especially since, if we liked, we need not spend a penny in this way. Poultry breeding is strangely neglected in England. We go on growling at the high price of fowls and fresh eggs, and yet the remedy is in our own hands; and while the prices were being brought down, we might eat our own fowls and eggs, and reap pretty little profits out of surplus stock.

A person interested in the subject has drawn up a balance-sheet according to which a capital of £400 laid out on 100 hens, their

housing, food, and other necessary expenses connected with them would yield a return of 570, *i.e.*, £170, profit in four broods of chickens at £125 per brood and ten tons of dry dung at £7 per ton. Here is another of his calculations. Five hens would cost say, 15s. their food for a year another 15s. During that time they would lay about 700 eggs, which at 1s a score, would yield 35s. or a profit of 5s. on 30s.—over 16 per cent.

And here is a third estimate. A man and his wife could take charge of 10,000 hens not for breeding, fatten and sell 3,000 every year, and buy the same number of young, which would begin in November, if hatched in the previous spring, to lay about four eggs a week each until next maulting. The hens' produce might be put down at from 120 to 150 eggs a piece per annum, which, at the rate of thirty a shilling, would yield a good profit.

It seems that when hens will not brood, capons and cocks can be induced to take their places as sitters; but cheaper than any animated hatcher is M. Carbonnier's incubator. In this eggs are laid on hay in a drawer placed under water raised to a temperature of 110 degs. by a colza oil lamp. This heat gives the eggs a temperature of 105 degs. or 104 degs., and like the warmth from the hen's breast, comes from above. All that has to be done is to keep the lamp burning, and to pull out the drawer twice in the twenty-four hours to turn the eggs, and to expose them for a quarter of an hour to the cooler outside air. The chick finds its way out of the shell unaided, is kept in the incubator for twenty-four hours after hatching, and is then admitted to a nursery provided with lambs' wool for the unfledged little thing to snuggle into when it feels cold. Forty eggs can be thus hatched at a cost in winter, of 3s. 6d., in summer of less than half that sum.—*Leisure Hour.*

OUR FOREIGN EGG TRADE.

THERE are in London, says a writer in the *Leisure Hour*, some hundred egg dealers, big and little. One of the largest of these is Mr. Auguste Le Miere of Clerkenwell, who allowed me to visit his place of business, where I was favoured with some interesting information. In the warehouse, a low-pitched chamber with a pillar-propped ceiling and a boarded office, a million eggs might be stowed away. It held, when I was there, eggs from Ireland—5,000 in crates; and in cases with battens instead of complete covers nailed over their straw, cases holding 1,440 and 600 a piece—eggs from France, Spain, Italy, and Hungary. Irish eggs are said to be about the best eggs going, far better than French, than which they would command a higher price if they were only packed more carefully. Italian eggs are also preferred to French, and are rapidly bringing down French prices. Italy will soon have a place to herself in egg returns, instead of being ranged with other countries. The house of which I speak imports five or six hundred boxes of Italian eggs a week. Next year it will have large supplies from Canada, that vigorious child which, for a consideration, provides her mother with so large a proportion, of her food—corn, beef, and mutton, dead and alive; ham, bacon cheese, canned fish, fresh salmon, and now eggs. Spanish eggs are exposed to this disadvantage. If brought over in the same hold with oranges, they become impregnated with an orange scent and flavour, and thus are spoilt as eggs. Eggs should be kept to themselves in cloistral seclusion. The proverb about their immunity from impunity is, as I have already pointed out, a delusion and a snare; they imbibe foreign odours and savours with the greatest readiness. If the cases are made of green wood the eggs will be ruined, and the some fate awaits them if the straw in which they are packed is not perfectly dry. It will ferment and communicate its fusty smell to the eggs. At Mr. Le Miere's depôt at Honfleur, the straw used for packing is turned over and over again in the sunshine, like mown grass meant for hay. This depôt is supplied with eggs by poultry breeders living within a radius of twenty miles round the town. At the depôt the eggs are sorted into extralarge, large, middling, small, and dirties. Eggs sent on commission are sorted by the senders. They have their money forwarded to them every Thursday. Eggs from the Azores are not favourites in the market, on account of their small size.

Most of the eggs imported come in steamboats either direct to London or else to the outports, from which they are hurried up to town by the London, Chatham, and Dover, South Eastern Brighton and South Coast, South Western and Great Western Railways. But small sailing vessels are still used, especially in summer. Mr. Le Miere has one of thirty to forty tons, which plies between Honfleur and Shoreham. Some 300,000 eggs a week pass through his hands, that is 15,600,000 a year. At the rate of 50,000 a day they are distributed in one and two-horse vans amongst the firm's customers chiefly London porkmen, buttermen, and cheesemongers. Very few are sent into the country, and none are sold to manufacturers.

Spring is the busy time in the egg trade. Christmas, in spite of its puddings, does not appreciably stimulate the demand. When asked whether it is possible to hazard a 'wide solution' of the question, How many eggs are used for puddings, &c., and how many eaten from the shell? The good-natured manager chuckled, and says that that is a riddle which passes his wit and anybody else's, he thinks; that customers do not tell provision-dealers what they are going to do with the eggs they buy. The average wholesale buying price of eggs is from 7s. to 8s. the selling from 8s. to 11s per hundred. Ducks, eggs are worth 1s. a hundred more than hens The egg hundred, it has been intimated, means 120.

THE FOOD OF PLANTS.

BY W. IVISON MACADAM, F.C.S.

(*Continued from page 54.*)

COMPOSITION OF FARMYARD MANURE.

	Fresh.	Rotted.
Water	71·0	79·0
* Organic matters	24·6	14·5
† Ash	4·4	6·5
	100·0	100·0
* Containing nitrogen	0·45	0·58
Equal to ammonia	0·54	0·70
† Containing potash	0·52	0·50
" soda	0·15	0·18
" lime	0·57	0·88
" magnesia	0·14	0·18
" phosphoric acid	0·21	0·26
" sulphuric acid	0·12	0·13
" chlorine	0·15	0·16
" silica	1·25	1·70

On association standards the above are worth about 10s per ton.

Sea-weed.—The weed cast up by the tide is much used in some parts of the country, more especially in the Highlands bordering on the sea. The following table gives an average analysis, which shows that whilst the nitrogen is very similar in amount to that contained in farmyard manure he salts are higher.

COMPOSITION OF SEA-WEED.

Water	80·44
* Organic matter	9·25
† Ash	10·31
	100·00
Containing nitrogen	0·45
Equal to ammonia	0·54
† Containing potash	1·95
Phosphoric acid	0·47

Bones.—We must then look to some other source of supply for manure, and this we find in the bones of animals, which consist principally of phosphate of lime and organic matters capable of yielding nitrogen, along with certain other materials of less importance to the plant. So as to render the bone more readily acted on, it is necessary to have it reduced to a fine state of division, and when so broken, the bones are known commercially by several names depending on the size of the pieces. The more common of these are—

½ inch bones.
¼ inch bones.
Crushed bones.
Bone dust.
Bone meal.

The following table gives the analyses of 6 samples of bone:—

COMPOSITION OF BONE MEAL.

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.	No. 6.
Moisture	7·36	9·68	9·63	7·41	8·46	9·16
* Nitrogenous organic matter ...	29·22	34·54	28·46	35·48	29·62	29·22
Alkaline salts	0·64	0·72	0·74	0·62	0·71	0·64
Phosphates	54·32	48 54	51·82	46·12	52·68	50.96
Carbonate of lime	6·78	11·08	6·64	8·69	7·91	8·58
Silica	1·68	1·04	2·66	1·68	0·62	1·44
	100·00	100·00	100·00	100·00	100·00	100·00
* Containing nitrogen equal to ammonia	4·58	4·86	4·56	5·12	4·81	4·26

Degelatinized Bone Meal.—When bone has been boiled so as to obtain the larger proportion of the glue contained in it, the residue after drying is readily pulverised, giving a coarse white powder, which is known as 'Degelatinized Bone Meal.' This material contains a higher percentage of phosphates, whilst the nitrogen is much lower than in pure bone. The analyses of three samples of this substance are given below:—

DEGELATINIZED BONE MEAL.

	No. 1.	No. 2.	No. 3.
Moisture	6·52	9·12	12·24
*Organic Matter	15·06	11·27	16·18
Alkaline salts	1·27	1·06	0·73
Phosphates	64·24	63·83	65·53
Carbonate of lime	10·65	6·87	4·39
Silica	2·24	7·85	0·87
	100·00	100·00	100·00
*Containing nitrogen equ, to ammonia	1·67	1·82	1·83

Fish Guano.—Another manure which resembles bone in supplying phosphate and ammonia is known as fish guano, and consists of waste fish scrap dried and ground. It is a fine meal, less rich in phosphates but with much more ammonia and salts than bone, and containing a lower percentage

of carbonate of lime. The higher class of fish manure is known as 'Polar Fish Guano,' whilst the 'American Fish Manure' contains less phosphates with more ammonia and alkaline salts than pure bone. The composition of these two classes of fish guano will be seen from the following tables:—

POLAR FISH GUANO.

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5
Moisture	10·54	9·98	8·48	5·72	10·18
*Nitrogenous organic matter ...	56·48	56·04	57·24	64·04	58·64
Alkaline salts	2·56	1·23	1·18	1·82	1·24
Phosphates	26·48	28·48	29·04	28·86	29·84
Carbonate of lime	3·06	8·48	8·63	4·54	4·12
Silica	0·88	0·84	0·43	1·02	0·98
	100·00	100·00	100·00	100·00	100·00
*Nitrogen equ. to ammonia... ...	11·15	9·81	9·90	10·21	10·12

AMERICAN FISH MANURE.

	No. 1.	No. 2.
Moisture	20·52	22·64
*Nitrogenous organic matter	57·16	49·63
Alkaline salts	1·98	1·36
Phosphates	18·52	15·44
Carbonate of lime	5·78	9·92
Silica	1·04	0·96
	100·00	100·00
*Containing nitrogen equ. to ammonia	9·08	7·96

In all the manures yet treated of it will be seen that the phosphates are present in the insoluble condition of the tri-calcic phosphate (Ca32PO.) and as such are not in a state to be readily taken up by the spongoles of the rootlets. The actions by which the plant assimulates these insoluble bodies into its system are not perfectly known, and the study of the subject is necessarily surrounded by much difficulty. Many theories have been advanced for its solution, some holding that the spongoles of the plant root have a special dissolving power, by which they take up their food. Others, on the other hand, declare that the carbonic acid contained in the atmosphere being washed down by rain, &c., seizes hold of part of the lime of the phosphates to form the carbonate of lime, at the same time rendering the insoluble phosphate soluble, and so allowing of its being dissolved by moisture, and passed into the plant structure. Another theory holds that the ammonia being oxidized in the soil into nitric acid, that that substance at the moment of its formation acts upon the lime of the phosphates to form the nitrate of lime, liberating at the same time the soluble phosphates in a condition fit to be of use to the plant. The two last theories assume the necessity of the phosphate being in the soluble condition before it can be of use to the plant. In practice it is found that, although a manure such as bone meal is useful where the effects are desired slowly and the results more permanent, yet a much more quick and ready manure is one which holds a certain amount of its phosphate in a soluble condition, and ready for immediate assimulation by the plant.

Guano.—Such a manure is obtained in a guano which is composed of the excrements and bodies of sea birds, which congregate in large colonies on certain islands, &c., more especially during the breeding season. These manures differ according to the country in which they are deposited, for if the climate be hot and dry, the deposit is quickly dried and disintegrated with the loss of only a small quantity of the nitrogen, and the result is a guano of the *Peruvian class*; whilst if there be much rain or sea spray, and the manure be slowly dried, there is an almost total loss of the nitrogen, and a guano is obtained of the *phosphatic class*. Besides these two extremes there are many intermediate classes depending on the varying circumstances to which they are exposed. The first or nitrogenous class contain a proportion of ordinary guano phosphates which is insoluble, along with a certain amount of alkaline or soluble phosphate, and a considerable percentage of ammonia. In this class the principal guanos now employed are Peruvian and Ichaboe, but there are other and less important sources. The composition of these guanos are as below:—

PERUVIAN GUANO.

	No. 1.	No. 2.	No. 3.	No. 4.	Mo. 5.	No. 6.

Dissolved Manures.—It will be remembered that in bones the phosphates are entirely in the insoluable condition. A more rapid fertilizer may be obtained by the addition of acid, which dissolves out part of the lime of the insoluble phosphate and leaves a soluble phosphate. The acid employed for this purpose is sulphuric acid, and according to the amount added, there is obtained a greater or less amount of soluble phosphate. The action of the acid is, that starting with the insoluble tri-calcic phosphate (Ca32PO4) and adding to it sulphuric acid (H2SO4) to the extent of two parts, there is formed two parts of sulphate of lime (stucco, CaSO4), and at the same time the hydrogen of the sulphuric acid replaces the lime in the phosphate, giving the tetra-hydric monocalcic phosphate or hydrated soluble phosphate of lime. The change may be expressed in symbols, thus:—

CaCaCa2PO4

H2 SO4

H2 SO4

=CaH42PO4+2CaSO4.

When only a small quantity of acid is employed, the resulting product is called 'vitriolated bones;' whilst if a larger quantity of acid is used, there is obtained 'dissolved bones.' In the first of these the amount of soluble phosphates may be as low as 3 or 4 per cent., whilst the insoluble phosphate is high. In dissolved bones the soluble phosphate is much greater and the insoluble phosphate less in proportion. The following analyses will show the composition:—

VITRIOLATED BONES.

Ammonia-Fixed Guano.—The addition of a small quantity of sulphuric acid to Peruvian guano causes the formation, with the ammonia of the guano, of sulphate of ammonia; and at the same time a portion of the insoluble phosphate is dissolved to the condition of soluble phosphate, and there is obtained a more rapid fertilizer. Besides this, the ammonia being fixed, it cannot escape as vapour, so that a loss of ammonia is avoided, whilst a manure is obtained in a more suitable condition for the use of the plant. Such manures are known as ammonia-fixed guanos; and the composition is given below:—

AMMONIA-FIXED PERUVIAN GUANO.

	No. 1.	No. 2.	No. 3.
Soluble phosphate	13·05	13·98	12·13
Equ. to bone phosphate rendered soluble ...	20·36)	(21·81)	(18·92)

Nitrogen in nitrates equ. to ammonia ...	0·46	0·41	0·56
Total nitrogen as ammonia	8·48	8·73	9·08

Besides these sources of both phosphates and nitrogen, there are many other materials used in agriculture to give a supply of either phosphate or nitrogen separately. The class of incomplete manures may occasionally be used with advantage, when the soil may happen to want one ingredient to make it fruitful. The sources of phosphate are not as a general rule used in their natural condition, as they invariably contain that constituent in the insoluble form. It will be necessary, however, to note the composition of the various substances used, so that we may more fully understand the manufactured article.

(*To be continued*)

RHEA FIBRE.

THE following are extracts from a report on the preparation and use of "Rhea Fibre," by J. Forbes Watson, M.A., M.D., LL., D, &c., in 1875.

(3).—*Cultivation of Rhea in Assam.*

With respect to the cultivation of the Rhea plant and the preparation of its fibre in Assam, I cannot do better than quote from Colonel Hannay's published observations, as well as from a communication received from that gentleman in 1859.

"The sole cultivators of this plant are the dooms or fishermen, who use it chiefly in making their nets; they cultivate it in very small quantity however, and as the fourth crop is that which bears seed, and they cut it down before the seed is formed, the plant is propagated entirely by dividing the roots. The ground is a small plot close to their huts, which they have great opportunities of attending to and manuring well with ashes and cow-dung, a quantity of which is essential to the proper growth of the plant.

"I have mentioned four crops; but as I have now a crop, the fifth, since planting, fit for cutting in February, and I see others belonging to the dooms in the same state, there will be five crops since planting, or six crops from April to April; the last or cold weather crops, cut in February, being considered to produce the strongest fibre. However, as moisture seems so essential to the quick growth of the plant, generally speaking, after the early November or fourth crop, the dooms allow the cattle free ingress into their plots, and it is thus kept down till February, when some plants are taken in opening out the roots, heaping up the earth, and manuring them, as well as enclosing a fresh the plot of ground. The soil from repeated manuring, is of course rich; and on this, and a good degree of shade and protection from storms depends the luxuriance of the crop, which I have been here eight feet high, and the extracted fibre six feet long. So much attention, indeed is given to length of stalk amongst the Kakoos of the Chinese frontier, that the gardens are walled in (with wattling) like a *pan* [*Piper betel*] garden.

"From the roots thus dressed up in February, a crop will be cut in April, another in June, another in August, and another early in November; the most luxuriant crops being those of June and August, as naturally receiving the greatest quantity of moisture. The fifth crop takes from early in November to February to come to maturity. Between the cuttings, all that seems necessary is a fresh opening up of the ground around the roots which in a regular plantation is best done by hoeing between the rows with a spade-shaped hoe set in a long handle; the person, as he performs this, going backwards so as not to step over his work,—in fact, nothing can be more simple them the cultivation on this plant, all that is required being a loose rich soil, and protection to the crop by a good strong fence. The roots throw up at least 12 shoots when in full bearing; should they increase, and the crops get too thick, the roots require to be separated; and by this means of planting out fresh ground and new plants from seed, the cultivation can be carried to any extent.

"The stalks are considered fit for cutting when they have become of a brown colour for about six inches above the roots. To cut them, the doom seizes the leaves at the upper end with his left hand, and passing the right hand down to the root, strips off the leaves. He then cuts the stem two or three inches from the ground."

(4)—*Notes on the cultivation of Rhea in India. By W. King, Officiating Superintendent, Botanical Gardens, Saharunpore, 1869.*

LIMIT OF GROWTH.—The garden in Dehra Doon is about 2,500 feet above the sea level, and the plantations in the Kangra Valley are probably higher. There are no exact records known to me, showing the height at which the Chinese nettle thrives best. It grows, however, freely in the plains at very low elevations. At Saharunpore, which is about 1,000 feet above the sea the plants are very green and healthy, and reach a height of five to seven feet.

SOIL AND SHADE.—The Chinese prefer a rather stiff soil; but I gather, from a communication in the journal of the Agri-Horticultural Society that in Assam a loose rich soil is considered the best. That in the Dehra Doon gardens is of the former description, whereas the patch of ground planted with Rhea at Saharunpore is rather light and sandy. My own experience, which however, is but limited, leads me to think moderate shade is an advantage. The finest plants in the garden at Saharunpore are a few grown under trees; and shade appears to be the only condition of growth in which these differ from less vigorous plants near them.

MOISTURE AND MANURE.—A good supply of moisture is undoubtedly required, and regular irrigation would be necessary in the plains. But of all the requisites for successful cultivation, I believe the first to be manure, and this is the one least recognized in Indian agriculture. The Chinese manure extensively. They plant out in soil which has been carefully prepared and richly manured. They also use liquid manure, and in the cold season give a top-dressing of stable litter.

PROPAGATION AND CULTIVATION.—The plant being one of those in which the male and female flowers are separate, and situated on different parts of the stem, the production of seed is uncertain in localities where the insects by which fecundation is probably accomplished are not indigenous. In district where Rhea has been *introduced*, propagation has therefore not been conducted by seed but by cuttings, and by division of the roots of old plants. By cuttings it may be propagated very easily as scarcely one fails to strike. During damp weather roots of old plants may be freely broken up into smaller ones, and these, if planted out into well-manured nurseries thrive well. This is the favourite mode of propagation in China. Both cuttings and fragments of root should be planted about 1½ feet apart. The soil between the plants should be frequently broken up so as to keep it loose and should, of course, be kept free from weeds. Top-dressing with manure is strongly insisted on by Chinese cultivators.

AGRICULTURE IN THE NORTH-WEST.

THE Lieutenant-Governor of the N.-W. Provinces has issued the following notification, dated the 29th January 1880:—

RESOLUTION.

READ—

Letter No. 194, dated 15th January 1880, with its enclosures, from the Director of Agriculture and Commerce, North-Western Provinces and Oudh.

OBSERVATIONS.—The Lieutenant-Governor has for some time been desirous of inducing the Talukdars' Association in Oudh to take into consideration the questions whether, and in what way, the interests of agriculture can be promoted by them, or by Government in co-operation with them, and of enlisting their active sympathy and aid in furthering any schemes which are likely to conduce to improvement in agriculture, and to the prosperity of the agricultural community, whether sub-proprietors or cultivators. There can be no question that the Talukdars can render material assistance in this direction, and the matter is one in which their best interests, as also those of the large agricultural community, are concerned. Many of them have capital which can be profitably invested in the improvement of their estates, and all can further objects recognised as useful and profitable by advising and aiding their tenantry, or adopting improvements on their home farms. Hitherto measures of this kind, if taken up in this country at all, have been originated by the Government, and have too often failed to reach the classes for whose benefit they were designed. But since the aid of

large landholders deeply interested in agricultural improvements is secured, advance cannot but be more appreciable and tend to a wider development of the agricultural resources of these provinces.

All the request of the Lieutenant-Governor and Chief Commissioner, the Director of Agriculture and Commerce accordingly placed himself in communication with the members of the "Oudh Talukdars' Association" at Lucknow, and preliminary meetings were held on the 20th November 1879, and 8th January 1880 when a definite programme was sketched. The main features of this programme are—

(1). That an annual meeting be held at Lucknow for the purpose of discussing questions of agricultural reform, and of instituting such action as after discussion may appear desirable.

(2). A special committee, consisting of the following members, has been nominated for the arrangement of business connected with these meetings :—

His Highness the Maharajah of Balrampore, *President*.
Rana Sankar Bakhsh, *Vice-President*.
Kunwar Harnam Singh.
Chaudhri Khaslat Husain.
Rajah Ajit Sing.
Mirza Agha Ali Khan.
Thakur Baldeo Bakhsh.
Shaik Imam-ul-lah.
Altaf Hussain Sahab.
Munshi Kali Prasad.
Munshi Newal Kishor.
Lala Ram Shankar.
E. C. Buck, Esq., C.S.
Major D. G. Pitcher, *Honorary Secretary*.
Shaikh Nasrat Ali, *Assistant Secretary*.

(3). The first general meeting is fixed for the 5th April 1880 ; and the points decided upon for discussion at it are—

(*a*) whether, and how far, by the action of the Talukdars, or of Government, or both, the extension of canal or well irrigation is desirable or possible, and, if so, by what means ;

(*b*) whether any steps can or should be taken for the improvement of cattle, or for the better supply of fodder in the province ;

(*c*) whether any system can be usefully adopted for the distribution of better seed ;

(*d*) whether the English plough modified to meet the conditions of this country is likely to be useful in Oudh agriculture, and how best to give the plough a thorough trial ;

(*e*) whether the arboriculture of the province can usefully be extended.

It will be open to any member of the Talukdars' Association to send to the Secretary of the committee any further questions of a general character for discussion.

Subservient to this meeting, as illustrating its object, affording substance for discussion, and tending to excite healthy emulation and competition, the committee have decided upon holding an exhibition of agricultural stock, produce, implements. The Lieutenant-Governor and Chief Commissioner has perused with much interest the papers now laid before Government, and cordially approves the measures proposed by the committee. His Honor is satisfied that the energies of the Association cannot be applied to a more laudable and useful object, and he will gladly contribute to the expenses connected with the meeting, and as far as possible aid the movement now started on a basis from which excellent practical results may be anticipated.

INDIA AT THE SYDNEY EXHIBITION.

THOSE who are able to find the space assigned to the most important of Britain's dependencies, which is by courtesy designated a court, first express surprise that such an important country should be so scurvily treated by those who had the division of the interior of the Palace. Had it not been for Major Clementi, the Government of India would have found a very good excuse for not naming a Commissioner for the Sydney Exhibition, in the disturbances which have recently taken place upon its frontier. Major Clementi, fortunately was a visitor to Sydney about the time the Exhibition movement was brought to a head, and through his good offices the Viceroy had a sum of money set apart for the representation of the Empire. Unfortunately, the powers that be, far from hailing such action as that taken by the visitor with pleasure, took advantage of some delay in the transmission of Major Clementi's credentials, and when they arrived, apportioned the angle formed by the galleries of the nave and eastern transept to the Commissioner, at the same time refusing to permit any partition to be erected, because the wall space had been assigned to a certain British paper-hanger. Nothing could be more incongruous than the exhibit of tawdry modern decorations and the quaint ancient style of those of the Great Eastern country. However, the gallant Commissioner has made a really creditable show, and those who visit his court will not regret the hour or two which passes as they are induced to linger over one interesting subject and pass on to others. Every one knows what the extent of the British Empire is, but few perhaps have really taken the trouble to look into the figures which demonstrate its enormous trade and resources. The revenue for 1876-77, for instance, was no less than £66,000,000, whilst the expenditure, including outlay upon productive public works, was £58,000,000. The private foreign trade return show a net excess of exports of the value of £18,109,747. The catalogue, which has but recently been issued, has a well written commentary upon these and other figures, whilst the industries are described and dwelt upon at judicious length.

Taking the classes in order, we find the Government of Madras exhibiting a number of chemicals, which include samples of castor oil, which is now so extensively used as a lubricator all over the world. Indeed it has done much to cripple the once famous whaling industry, which employed so many British, American, and Colonial ships. Cocoanut oil is also largely traded in, whilst the industry of the natives of Malabar, in the preparation of fish oils, is shewn in three samples taken from the horned shark, and short shark. Indigo is of course an immense article of commerce, and in 1877 the exports of it reached £2,962.786. Some excellent photographs show the process by which the raw material is compressed, and in a glass case are to be seen blocks of the article ready for foreign shipment. Native pottery is always regarded with delight by those who have a taste for displaying curious articles in their drawing-rooms ; consequently many visitors regret to find that the agent here for Messrs. Watson & Co., of Bombay, has altogether neglected to furnish particulars concerning the very handsome exhibits which appear in a large glass case. The same may be said with even more force respecting the unique carved blackwood furniture which Messrs. Watson & Co. have forwarded. A suite of this has for some time had a place in the avenue downstairs, and numerous expressions of curiosity have from time to time been heard as to the country which produced such really beautiful furniture. Considering the very rough and rude character of the tools which the natives employ, the carving is wonderful. From the North-Western Provinces a number of cotton fabrics have been sent, to show the capacity of the people in the direction of manufacturing clothing suitable for hot climates. The Muir Mills Company, of Cawnpore, send various patterns of drill, which have been strongly woven. Some chequered and striped cotton goods from the Elgin Works, of the same town, are of a pattern very much like Shepherd's plaid. Hitherto, our principal trade with India has been cornsacks and wool packs—very useful articles, no doubt, but hardly of a character to monopolise the relations of two countries affording such wide fields for the interchange of products. Lady visitors always find their attention arrested by the Cashmere and other shawls from the North-Western Provinces. These are really beautiful articles, the tints being very bright and gratifying to the eye. One fawn-coloured shawl deserves special notice because of its exquisite braiding. Grey vampire, a species of satin, is also of rich texture and colour, Azamgarh fabrics, which are a union of silk and cotton are very neat. The ash colour is well tinted. In the same case are found a quantity of very fine muslins, which would be of great utility for making ladies' dresses here. It is used by the natives for turbans. The Government of Madras is responsible for the exhibit of cinchona bark, which is so largely exported for making quinine. A number of carpets are suspended from the roof, but only in one instance can it be discovered what a great depth of "pile" they have. They have been made in the various gaols of the Empire, and in two of them the Persian pattern has been adopted. Already the best of them have been bespoken. Messrs. Watson & Co., of Bombay, whose exhibits in other classes we have previously noticed, show some handsome inlaid sandalwood dishes, and other useful articles which may also ornament drawing-rooms. A work-box, inlaid with pearl, which is exhibited by Messrs. Cruvance, of Bombay, is a splendid article, every inch of its surface being a study. Benares engraved brassware is shown profusely, not only by the Government of the N.-W. Provinces, but also by Messrs. Lassetter & Co., of this city. It is all remarkable for the extent and beauty of the chasing, which has been affected by the natives. Major Clementi has placed a white marble card tray, of mosaic design, which the natives follow as closely as do the Italians ; indeed it is averred by many persons that the celebrated Taj Mahal at Agra was the work of the latter, and that the Hindoos make this the copy for most of their work. Tobacco is of course largely grown and manufactured. The exhibits, however, is confined to cigars, of which a great many descriptions are shown. We understand that small Havana shaped cigars are sold as low as 24*s*. per 1,000. Tea is perhaps the greatest object of interest in the court, and strenuous efforts are being made to prove how extensive is the trade carried on in this respect, no less than 116 being catalogued. We find that the value of this article as exported in 1876-77 was £2,620,140. Large quantities of Indian tea are sold by our own merchants, but our retailers nearly always describe it as Chinese. Seeing the difficulties which the Celestials are ever and again throwing in the way of our traffic with them, it certainly should be the aim of all our traders to patronise the Indian article, more especially as it will be proved that it is as good as anything grown in the Flowery Land.

The best crop is produced in Assam, at an elevation of from 2,000 to 3,000 feet. One sample from this district, an orange Pekoe, priced at 12*s*. per lb. has such a strong and fragrant aroma that it does not appear to possess any when re-applied to the nostrils. Coffee is shown in almost every form, and admittedly of finer quality than anything displayed from other countries. Preserves, pickles, condiments, and jams are of course to be looked for, and there is certainly no lack of them. Messrs. Clifford and Love, of this city, show a fine collection, which, in addition to samples of tea, contains various preserves which were not specially prepared for the Exhibition. The chutney shows the fruit, and is very tempting. We find mangoes pickled, preserved, jellied, and in fact bottled in almost every possible way. Curries are here in galore. Jam is represented, made of pineapples, mangoes, plaintain, tamarind, and guavas. A number of sauces and high relishes also find places, but we regret to learn that the firm's last ventures in these articles had to be transferred to Queensland. Bass & Co.'s India pale ale has of late years been losing so much ground in India through the superiority of the local brews, that the importation of this once celebrated beer is reduced to a minimum. The Murree Brewery Company,

Punjab, supply the troops in India with the article that is exhibited bottled form. It is designed to keep any length of time, and is merely exhibited for competition, because the demand is already greater than the supply. Samples of sugars grown and prepared in the North-Western Provinces invite special attention because of their purity. They can be supplied in large quantities at a low rate, seeing that labour is so cheap. The famed cleanliness and patience of the native are guarantees that every care has been taken in the preparation. This exhibit should attract the attention of dealers in sugar, though there is much ground for the assertion that is often made that the trade in Australia is greatly monopolised. In conclusion, we must congratulate Major Clementi on the success which has attended his efforts, notwithstanding the many impediments he found in his way.—*Sydney Daily Telegraph.*

ON THE CYCLAMEN.

THERE are few more attractive winter flowing plants than the various winter and early spring flowering cyclamens. They combine the charming features of neatness of growth, foliage of handsome form and coloring, and flowers of most elegant structure and brilliant colours. The flowers in all the species, but especially in the varieties of the Persian species, which are most extensively grown for greenhouse and conservatory decoration, are very profusely produced. It is no unusual thing, under skilful treatment, to see as many as two hundred fully expanded flowers open at one time in a flowerpot of six inches diameter, and as many more to follow peeping up amongst the beautiful leaves. These are gems of the first water, simple in character, but all the more attractive because they are so.

With the exception of *C. persicum* and its innumerable varities, and *Crepandum*, which must have the protection of the greenhouse, and during the growing season are benefited by a little more warmth than even the greenhouse affords, all the other species in cultivation will bear with impunity the temperature of our outdoor climate. Cold is not the worst enemy to fear in the management of cyclamens in the open air; damp is much more destructive of them than cold, so that they should, when an attempt at their culture is made out of doors, be specially provided for in the matter of drainage, and, as far as possible, also protection from drenching rains in autumn and throughout the winter should be afforded them. But though hardly enough to endure out of doors, it must be stated that there are very few parts of the country where the beauties of the plants may be seen unmarred and in perfection. The uncertain and variable weather which we experience during the flowering period of most of species, is apt, in the majority of seasons, to lead to the destruction of the flowers before they expand, or to destroy them prematurely after they have expanded; so that, after all, it is better to treat them as plants requiring protection than as hardy plants; if we would enjoy their beauty to the full. A cold or unheated frame or pit is all that is required by the hardy species, which are the most numerous, and in their way not inferior in beauty to the more floriferous *C. persicum* and its varieties. A cool greenhouse may be made very gay with these hardy species during the winter and spring months, by having a good store of them in a cold frame.

The soil in which these plants thrive best is a good yellow loam, such as may be obtained from the top spit of old pasture. It should be the best that can be got, and should be further enriched by being incorporated with a third part of sheep or cow dung, the mixture being made up not less than three months before it is required for use. To this, when it is to be used, add a good allowance of sharp river or pit sand to render it porous. The spots should be well drained, and the soil must be made very firm round the roots. The last instruction refers only to roots of some age; small or very young roots should not be potted so firm. Having indicated the kind of structure and the soil in which these beautiful flowers may be cultivated successfully, so that their beauty may be thoroughly enjoyed without that liability to disappointment which attends their culture in the open air, we will treat of their propagation and culture from the seedling state to the fully developed plants.

The only successful means of propagating cyclamens is by seed. Some have attempted increasing them by means of division of the corms or roots, but with very indifferent results; it is a slow and unsatisfactory method, even when most successful. The seeds should be sown as soon as they are ripe. Shallow pans well drained are the best form of pot, to sow them in. The soil should be composed of equal parts of the loam above referred to, and leaf mould well decomposed, taking care to pick small sticks, beech-nuts, and other woody matters likely to breed fungy, out when turning it over. Sow the seed thinly on a smooth surface, and cover them with the finer portions of the compost to the depth of their own diameter. Water them and place a square of glass over the pot or pan, so as to cover it completely and prevent unnecessary and rapid evaporation. They should be shaded during bright sunshine to prevent their becoming scorched while the process of germination is going on, and care must be taken never to allow them to become very dry or to become saturated with wet while they are in the seed-pans or indeed at any period of their growth. A mild hot-bed will facilitate germination, but it is not essential in the case of the hardy species. The persicum varieties, however, must have heat while germinating, and it should be continued to them till they have attained size sufficient to be placed in their first pots from the seed-pans; but when they are established in them they may if it is summer, be kept in a cold frame. But as the sowings of these are sometimes made in September, they will require to be kept in a temperature of 50 to 55 degs. throughout the winter. Returning to the hardy species, their treatment should be carefully attended to from their first appearance above ground. Keep the seed-pans close to the glass, admit every ray of light except direct mid-day sun, which would be destructive to them. Dew them overhead night and morning with water from a fine rose watering-pot. As soon as the plantlets are fit to handle, let them be pricked off singly into small sized pots,—thumb or two-inch pots being the proper size,—using the same compost as for the seed pans, and draining the pots well. Return them to the frame, and for about a week after, they must be kept close and shaded during the brightest and warmest part of the day. At the end of the week begin to admit air by degrees day and night, and gradually discontinue the use of shading till its use may be dispensed with wholly, except during the three hottest hours of the day. Dew the plants morning and evening, as before directed, overhead, and continue this treatment till late autumn, when they begin to manifest a cessation of growth, and may be allowed to become gradually drier at the roots. During the course of the growing period they should be shifted into larger sized pots according as they require; never allow them to become pot bound, else they will cease growing. At the same time avoid over-potting the plants, one of the greatest errors that can be made is giving too much pot room. They make comparatively few fibres, therefore want but little pot room, the corm being the principal feeding part, and in which the assimilated food that is to go to the development of the flowers and leaves is stored up.

Established plants should be treated precisely in the same way as seedlings after they have been taken from the seed-pans, with the exception that they will require less shading. They will require to be turned out of their pots in autumn, or immediately before growth begins, to see the condition of the roots, which, if not satisfactory, should be improved by repotting or redraining, as the case may require.

The principal hardy species are as follows:—

C. coum.—Of which there are two varieties besides the normal form with bright red flowers, one being white, the other blush or light pink.

C. europœum.—An autumn flowering species, with variously coloured flowers, white, red, and purple; some individuals producing flowers combining all these colours.

C. hederæfolium.—Another autumn flowering species, with, as the name implies, ivy-like leaves. The flowers are rosy-lilac.

C. ibericum.—A very distinct sort, flowering in March and April. The flowers are variable in colour, rose and white being the predominating shades, having a dark crimson blotch at the base of each lobe of the corolla.

C. vernum.—A very beautiful but diminutive species, with deep crimson flowers—*N. B. Agriculturist.*

OUR AGRICULTURAL CONDITION AND PROSPECTS.

IN an almost purely agricultural country like India the well-being of the people depends on the land; and as the rainfall is concentrated into a period of a few months, the character and distribution of the rains make themselves felt in every part of the social fabric. During the rainy season of 1879, the rainfall was more than the average throughout the country generally. The consequence was that the autumnal harvest failed to a large extent from too much rain; but the vernal harvest, owing to the great qauntity of moisture in the soil, will be an abundant one in every part of the country. The cotton crop in the principal cotton-growing districts has largely failed from the effects of the severe cold in the early part of the winter—the plants having been bitten by the frost and stunted in their growth and increase. The other crops, especially the cereals, are in excellent condition, and will produce on the whole a full average yield.

It is certainly the first duty of Government in such a country as India, where its main source of revenue is the land, to provide all feasible advantages and facilities for the most productive cultivation. Much is now being done in every part of the country for the storing and distribution of the rainfall. Our large irrigation reservoirs with their systems of canal distribution are greatly increasing the productiveness of the soil. The great advantage of this to the country may, however, be counteracted and thwarted in two ways: first, by a too heavy land-tax. It has been satisfactorily proved that the settlement in this presidency has been injudiciously and improvidently high. The land has consequently been frequently changing hands, getting out of the hands of practical agriculturists into those of mere money-lenders, who employ the agriculturists as mere farm labourers who have no interest in the improvement of the land nor in its increased productiveness. The Deccan Ryots' Relief Act is not going to effect any improvement in this direction. Some flying straws have already shown how the wind is blowing from this Act. The ryots must and will have money. They can only get it from the sowkars or money-lenders. These latter have now discovered, as everyone who knew anything about them foresaw that they would discover a means of lending money to the ryots without restriction, and in spite of any provisions of the Act to their disadvantage in so doing. A money-lender says, in answer to the solicitation for a loan,—yes, you can have what money you want by simply transferring your land to my name. Debt-bonds and mortgage-bonds will now be out of fashion, and deeds-of-sale will come into vogue. These will be duly registered. And Dr. Pollen's occupation will be gone; or, if not absolutely gone, it will simply lead to further litigation which will be wholly in favour of the money

lenders. This state of things, so favorable to money-lenders, is intensified by the following measures : when the assessment is not paid by the ryot, his land will not be sold by public sale, but it will be resumed by Government. The ryots will greatly prefer to get money from their savkars by transferring their lands to their names—that is, by deeds-of-sale, than to have their lands resumed by Government and thus pass out of their view for ever. The savkars promise that when the loans are paid off, the lands will be restored to their former owners. The ryots will always believe that they have better chances of getting back their lands by transferring them by deeds-of-sale to the savkars than by allowing them to be resumed by Government. Thus this Relief Act will afford no relief to the ryots ; and therefore it will not remove the existing hindrances to production notwithstanding the great advantage afforded by our irrigation systems. A very different state of things exists in the Central Provinces as regards the land settlement. The present Chief Commissioner was the original Settlement Officer of those provinces. The assessment was designedly fixed so low that the agriculturists might not feel it a burden. They have never felt it to be a burden. Government has itself done much to improve the land, and has afforded great facilities to the landholders to do so themselves. The result will be that at the approaching renewal of the settlement the revenue will be increased by about Rs. 4,000,000 without the agricultural population feeling it. Secondly, the advantages to greater productiveness of the land afforded by our water storage and distribution may be counteracted by expense of carriage to market for export produce. Some of the best wheat growing districts are the Berars and Central Provinces. The growing crops there are in the finest order and promise magnificent yields. The growers, however, cannot afford to sell their wheat at the price at which it requires to be laid down in Bombay, in order to compete with that of other countries in the English market. The railway charges for carriage are too high to admit of Berar and Central Provinces, wheat being laid down in Bombay at remunerative rates. This is a very serious matter this year, when the supply of wheat here will be so great and the demand in England unprecedentedly great. Of wheat-growing countries only the United States of America, Canada, Australia, and little Denmark have produced an average yield in 1879. The average production for the whole of Europe is 962,866,150 bushels, while that of 1879 is only 763, 987,500 bushels, being a falling off of 198,878,650 bushels. The average yield for other parts of the world—that is to say, the United States, Canada, and Australia, is 1,367,687, 500 bushels, and for the past year, 1,189, 487,500 bushels showing a decrease of 178,400,000 bushels. The deficiency of the crop for the whole world (not including India) is 377,279,150 bushels. The average yield of Great Britain is 83,500,000, bushels, and the yield for 1879 was 47,500,000 bushels. Great Britain, then, has to get 36,000,000 bushels from the rest of the world and can only look to America and Australia besides India. The whole average yield of Canada and Australia is only two-thirds of Great Britain's deficiency. France, Spain, Italy, Belgium are almost each of them as badly off as Great Britain as regards deficiency of yield. Indian wheat, moreover, is a favourite in the English market—preferred to that of any other country. If therefore the wheat-growing districts could lay down their wheat at the seaport at remunerative rates. for the exporters, India would have a certain market for her forthcoming yield of wheat. The railway charges, however, do not admit of the wheat from the best wheat growing districts being laid down in Bombay at such rates. What is true of wheat in this respect is also true of cotton. This article is selling in Berar and the Central Provinces at Rs. 140 a khandi ; the price at Bombay is Rs. 145 a khandi ; it cannot be laid down in Bombay at the price at which it is selling there. If the railway charges for these articles were less, the traffic in them this season would certainly be unprecedently great. If producers cannot afford to sell at rates remunerative to dealers, they may as well not produce, and all the advantages afforded for greater productiveness of the land are in vain.—*Deccan Herald.*

OUR RYOTS' AGRICULTURAL CUSTOMS.

THE vast majority of persons who know, or think they know, anything of India, its inhabitants, and their customs, look on the latter as so time-honored that any alteration of them is not only difficult but undesirable. A few are aware that trained English agriculturists consider most of them conducive to the exhaustion of the land, and consequently to a decline in the material prosperity of the agricultural classes, and, as these form the bulk of the population, to the impoverishment of the Empire. Some, who from long residence in rural districts consider themselves authorities on all matters brought within their observation, boldly assert that the trained men's views are wrong, forgetting that while the man with local knowledge may know the essentials of native cultivation better than those who make but hurried tours through a district, his knowledge is not equivalent to a thorough acquaintance with the principles on which agricultural science is based, combined with observations of the result of the application of those principles in England and of observations of the disregarded in India. The idea that every one may make a farmer, however worthless he may have proved in other occupations, is, we presume, the origin of the belief that the observations of trained agriculturists are scarcely worthy of attention when applied to native agriculture ; but a consideration of only one practice—let us take that of manure manufacture —in which the customs of scientists and ryots are so divergent, may prove that after all the former may be of use to India, if he be allowed sufficient latitude.

Roughly speaking, the ryot gets two loads of manure per annum per head of cattle kept, and by burning this he gets fuel gratis ; he gets also some 500lb. of grain per acre. The experimental farmer gets twenty loads of manure per head of cattle, no fuel, and 2,000lb. of grain under similar conditions of land and climate. Now is fuel gratis equivalent to 1,500lb. of grain per acre, when wood can be purchased in Madras at Rs. 7 per ton, and could be grown for nothing if that wasted article, a ryot's spare time, were properly utilized ? There can be but one answer to this, and as the difference in result is due in a great measure to the different practices, we believe they are worthy of attention. To take the ryot's first. We are all familiar with the sight of women collecting the droppings of cattle, and the bratties drying on the walls of the mud hovels of the villagers in which he cattle are tied up at night, standing on the bare floor. The little heaps of rubbish and ashes on one side of the hovel is also too general a sight to need comment, and if our journey in the mofussil be taken before the sowing season, the little heaps of manure, few and far between, attest the attempt of the ryot to make his small supply cover as large an area as possible; but even with the aid of sheep folded on the land, Mr. Robertson showed that, in the Coimbatore district for instance, 75 per cent. of the land receives no manure at all. The friends of the ryot assert he uses green leaves and deposits to eke out the supply, and thus manures his wet lands ; but those who know the presidency must be aware that while such a custom prevails the exuberance of vegetation is never so great as to allow any considerable area to receive such a benefit. We asserted that for twenty loads of manure made on a Government farm but two are made by the ryot, and these he frequently reduces to ashes.

The next inquiry is naturally the relative value of the two products. That on the Government farm, being made by keeping the animal in a sunken pit on litter, allows the liquid as well as the solid excreta to be utilized, but as the beasts are kept under, over, no moisture from rain can get into the pit, so that an undue dampness, which might be injurious to the hoofs of the stocks is avoided, while their trampling about free in a stall so condenses the manure and litter accumulating under them that no injurious exhalations are given off. Some months since the *Gazette of India* published an experiment from the Bangalore Experimental Farm that proved conclusively the approximate relative value of manure thus made, contrasted with the native methods of its manipulation. Cattle fed on grass only were kept in the sheds, and from a grazing ground manure was collected and stored in a heap. Equal weights of each were taken, and an equal weight of native-made manure burned, and the ashes applied to the land. The results over an unmanured plot of equal area with that manured were as follows :—

		Grain.	Fodder.
Cattle box manure	...	÷ 74 per cent.	+ 71 per cent.
Dry cattle dung ...	...	÷ 83 do	+ 26 do.
Ashes ...	...	× 37 do	— 20 do.

the action of ashes in lessening the yield of fodder being due to the forcing nature of its action, by which the production of grain was hastened at the expense of the growth of the plant. So much for the relative value of the manures in a first crop. On a second, their value was tested at Sydapet, where it was proved that the ashes affect only a single crop to any appreciable extent while the cattle-box manure has a lasting action, extending over more than one crop. In this case, the soil being lighter, the ashes forced a heavier crop, fodder only being grown, than was given by the cattle-box manure ; but in the long run the total yield was in favor of the cattle-box manure. The mechanical value of the organic matter in the manure in assisting the soil to absorb and retain water would also be lasting, and increase with each additional manuring the field received. As we pointed out in a recent article, when commenting on the excess of water, the ryots use for paddy cultivation, an addition of five per cent. of organic matter to a soil is, according to its composition, equivalent to between a third and two-thirds of an inch of rain.

If we want further proof of the value of manuring with a lasting manure, such as cattle manure combined with organic matter in the form of litter, Mr. Lawe's experiments at Rothamstead prove that while land that formerly yielded 30 bushels of wheat, say 1,800 lb. per acre, when farmed as farming was conducted in England forty years ago, it has now decreased its yield when left without manure to 8 bushels of 480 lb., while with continuous manuring the yield has increased to 3,600 lb. per acre. With such facts before them, why is it the Government do not make some attempt to set them before the ryots. There are no conditions that they cannot overcome. Mud exists to build walls for buildings, and grass to thatch them. Litter can be procured in many districts simply by cutting coarse grass. There is no reason why the liquid excreta should be wasted by evaporation ; its collection interferes with no caste prejudices. As to the loss of fuel that would occur if bratties were not made, Mr. Benson has clearly pointed out the ease with which casuarina trees may be grown for fuel to supplant their use ; and if once the order were given, for tree planting, and insisted on by the proper authorities, things would soon slide into an improved groove. Roadside tree-planting, by which the roads of Mysore may be traced until lost in the misty horizon, were but the result of an order of Mr. Bowring when Chief Commissioner, and who can say that their growth was a harsh measure and is now unpopular with the ryots. The people of India are so plastic when once a thing becomes a custom that we have no fear but that, were the planting insisted on, it would follow as a

matter of course; but alas! the order never comes and the hapless country is allowed to steadily, if almost imperceptibly, decline, because our rulers will not adopt reasonable measures for securing Nature's own fuel supply in India.—*Madras Mail.*

RAILWAY CONSTRUCTION IN AMERICA.

In my letter of last week I sent you a report of an interview with a prominent iron merchant, who in speaking of the probable mileage of railroads to be built next year, said it might exceed 7,000 miles. Such estimates always have an element of uncertainty, but from a subsequent and more thorough examination of the matter, I find that the generally accepted figure is much higher than that named, namely, 9,000 miles. Should this enormous total be even approximated it will explain whatever is mysterious in the present excited and abundantly prosperous condition of the iron trade. This alone would involve an enormous and probably unprecedented consumption of iron. Nine thousand miles of new railroad would consume, for rails, fish-plates, spikes, and bolts, not less than 15,000,000 tons of metal. It is expected that at least 125,000 cars of all descriptions will be built next year, which will consume 500,000 tons; 160,000 tons of iron will be needed to repair old cars, and enough new or re-roled rails to repair 10 per cent. of the 90,000 miles of railroad in operation, which will be equivalent to building another 9,000 miles of road, so far as iron is concerned. Without this last item, which is to some extent off-set by the quantities of old iron to be turned in for remanufacture, we have an estimated consumpcion, on railroad account, of 2,460,000 tons. We may, I think, safely accept this figure if, to cover all possible exaggerations, we leave out of account all consumption for locomotives, bridges, and telegraph wire, as well as the actual loss of iron in dropped links and pins, which never find their way back into use. It should be remembered that the railroads will also consume considerable quantities of iron in depôts, water piping, pumping machinery, and tools of all kinds. Indeed, 2,500,000 tons would seem to be a low estimate of the amount of iron which will be consumed by the railroads in 1880. Now, as I remarked in a previous letter, activity in railroad building has always been attended with general prosperity and activity in nearly all the trades which consume iron largely. The building of a new road in any direction induces settlement along its line, which means the building of houses and the sudden up-spring of villages and towns. However cheaply and quickly such houses may be built at first, they use more or less hardware, nails, and screws. It also brings into communication with the markets a greater or less extent of new land, which is quickly brought under cultivation. This calls for agricultural machinery, implements and tools. Every family needs a new supply of cooking and heating stoves, each weighing from 100 to 300. In fact iron in its innumerable forms is the first requisite of a new community, and such new communities are found establishing themselves along every new line of railroad which traverses good farming districts. This will be better understood from an examination of the actual figures in certain localities. From the land office reports it can be ascertained that during the 10 years closing June 30, 1879, the Government sold for cash 57,660,970 acres of land besides large grants under the Homestead Act. Mr. Robert P. Porter, a careful collector of facts and figures, writing in a recent number of the *International Review* upon this subject says:—"The present immigration, especially, perhaps, in Minnesota is unparalleled in the history of any of the States, and is accompanied by a demand for railroad and public land unprecedented. The offices of the Northern Pacific, St. Paul and Sioux City, and other railroads with lands to dispose of are daily crowded with applicants for the purchase of new wheat lands in the Dakota region, while the Government is literally besieged with claimants under the homestead and pre-emption laws in a manner surpassing all previous experience, even of the great immigration West from 1856 to 1857. During the three months ending November 30, 1874, the different land offices of the United States Government in Minnesota disposed of 429,467 acres. The railroad companies sold in the same time 589,186 acres of land in Minnesota and Dakota. In all, over 1,000,000 acres of land were appropriated to actual settlement in the two Red River, States in these three months and most of it in the immediate water-shed of that river. The general summary for the quarter ending March 31, 1878, in the district of Minnesota alone showed a sale of 1,207,871 acres. In 1871 there was scarcely a settlement along the route of the Northern Pacific road either in Dakota or the Red River Valley. Within the past year or two all this is changed. The district it travels is now enlivened by the influx of settlers whose houses, stores, schools, churches, and other appliances of civilised life are dotting the surface in all directions, and during the past year 250,000 acres of land have been opened for cultivation, and 65,000 souls have been brought into the country, to which hundreds are being added every day." But Minnesota is not the only State where such figures might be compiled by the careful investigator. Similar scenes may be witnessed all over the Western country, which is bustling with life and activity. Migration partly accounts for this, and immigration partly. There have been 134,053 immigrants entered at the port of New Your alone during the 12 months ended with November, against 120,000 for the same time last year. Nearly 6,000 men came this year who were not classed as immigrants, and of which an uncertain percentage will remain. I have no figures for other ports, and none for the immigration from Canada, which if not large, is pretty steady. Besides these additions from foreign sources, we have what amount to additions from within—the sub-division, of families by the marriages among the youths and maidens who leave their parents' homes and start out life for themselves. Of this class there is a constant westward flow, which does not weaken the older and more densely-settled portions of the country. Such a gradual redistribution of population is in the largest degree beneficial to the country, increasing the number of active producers, and swelling the aggregate of the national wealth. Meanwhile the whole country is prospering, with no element of weakness visible in any part of our business system. Such activity of railroad building necessarily sets in motion a vast aggregate capital, mostly paid out in wages to labour, and filtering back again through the countless channels of trade into the banks at the great financial centres. Such a movement is practically a stimulated circulation of the nation's life-blood, which courses through the veins and arteries of trade, throbbing at the pulses, vitalising the remotest extremities, and surging back again to the great heart, to be itself re-vitalised and again set in motion. If these somewhat confident predictions are warranted by facts and probabilities, as I believe them to be.—*Correspondent of the Ironmonger.*

THE BARRINGTON GOLDFIELD, NEW SOUTH WALES.

(Communicated).

This new goldfield is situated some 150 miles from Sydney and covers an immense stretch of country, but the parts most in favour at present are the Back Creek diggings. The field presents a far different appearance to what it did when it was first opened; at that time there were only a few diggers fosicking up and down the creeks. Our party struck a reef at 42 feet level, where the very place is now surrounded all round by claims. The greater part of the population is gathered round the township of Back Creek, where only a few months back but a few prospectors were camped. Back Creek would be known as a digging township if there were no signs of digging near it. The wooden buildings have been rashly thrown together, the streets badly laid out and with no regard to levels, and everything presents the appearance of a rush. It was daylight when I arrived after riding some 30 miles during the night, and there were crowds of loungers about the bars and in front of the public house doors. Generally speaking, this would indicate prosperous times. Diggers unfortunately imbibe in proportion to the gold they get. But as I will have occasion to show, there are many miners so-called at Back Creek who are too lazy to work, too lazy even to earn honestly the money they recklessly squander. In too many cases do they prefer to sell share in leases they have only applied for choosing rather to live in idleness than prospect their ground. These are the loafers, these are not the men who have made Back Creek what it is and will make it I think before the end of this summer the greatest goldfield in New South Wales. There are men about Back Creek pioneers of the good of old stomp who have lived on wallabies and wallaroos, dollying and crushing enough gold to keep them alive while crushing machinery was being erected. These are the men to whom Back Creek is indebted for its present condition.

My first night on the Creek gave me time to look around and make a few inquiries. The nights are usually spent in rivalry. Drinking and card playing are great amusements, and added to these there is a skittle alley. Let no one picture Back Creek as a large extent of canvas tents—most of the buildings are of wood, and considering its proximity to Sydney this is as it should be; and there are evidences of civilization that would not be met with on any of the remote gold fields in Queensland.

After having a good look round the field and having inspected the principal claims I have very little hesitation in saying the Back Creek has a brilliant future in store for it. Let no poor man go there, it is not a poor man's field. The ground on all sides is taken up and not worked, the mining regulations in this colony allow this, whereas in Queensland, in Victoria, not an inch of ground can be taken up without working it. This is the blight of faulty mining regulations, encouraged by the mining department of this colony. Many men have gone to Back Creek willing to work, men of experience, men of energy, and men with means sufficiently ample to weather, a few months' bad luck, but the opportunity has been denied them The loafers at Back Creek; who either expect to sell shares to new comers and expect the gold to be taken out for them, or hope to delude speculators have fastened on the ground. Many of the leases that have been applied for have never been surveyed, and many that have been surveyed have never been granted. Another drawback to Back Creek is the deficient and defective crushing machinery, for I am certain that a great deal of gold is lost in the process of crushing. But worse than all, the crushing power falls far short of requirements. There are only three batteries with ten heads of stampers each, capable of crushing 100 tons of quartz each per week.

That falls far short of what is wanted. I am certain that at last 2,000 tons of stone are raised weekly. A finer field for the erection of crushing machinery has rarely presented itself—a good supply of wood and water. The rate for crushing is 20s. per ton, every bag of quartz being weighed; and this may be considered high seeing that quartz in many of the Victorian goldfields can be crushed for 10s. per ton. Looking at Back Creek generally, the goldfield present a perfect net-work of reefs, several of which are payble, but most of them have not had time as yet to be proved. The reefs are high in the ranges and they are thickly timbered, which affords great economy for the working of the shafts and the field generally. At present as high as 11s. a ton is paid for carting the

quartz to the batteries. It is estimated there are over 2,000 miners on the field, and should some of the new reefs turn outwell, there is not the slighest doubt but that the population will be doubled before long. Considering its proximity to Sydney good roads might easily be made, as the goldfield is only about 50 miles from the railway, and most of the miners have swagged it, and swaggers are to be met daily on the road. A few speculators have come to the field of late, but from hearsay they have not seen the field in the same light as it has been represented. No doubt there has been and will be a lot of blow. I know of an instance where claims have been reported to be extremely rich, and when the quartz has been crushed it has been proud that they did not consider it payable.

Back Creek is divided into a right-hand branch and a left-hand branch. The latter has been most worked, and by far the largest amount of gold has been obtained from it. Here and there on the ranges abandoned shafts told their tale of failure. A time may soon come when 20s. a ton for crushing and 11s. a ton for carting will be relics of a bygone period. The first line of reefs is known as the Melbourne. The claim is held by three men, who are down with their shaft 60 feet. The last crushing gave them at the rate of 4 oz. to the ton, and in one piece of stone weighing 11 oz. 9 oz. of gold were got. The No. 1 South-West have had two crushings of 128 and 129 tons respectively which averaged over 8 oz. to the ton ! there are 18 men in the party. On the Mechanics' prospecting claim, there is also a shaft some 150 feet down with a lode 3 feet wide, which has yielded as follows :—9½ tons of quartz 4 oz. to the ton, 74 tons 1⅜ oz. to the ton. The Hidden Treasure claim is one of the best at Back Creek. On the Tunnel the lode has averaged about 2 feet and the returns have been as follows :—112 tons, 286 ozs. ; 85 tons, 106 ozs ; 112 tons, 288 ozs. There are only five shareholders in the claim, but eighteen men all work night and day. In connection with the Hidden Treasure reef, there are about it greater indications of permanence than about most of the others. The walls are of nice slate with clay and soft slate between that and the reef; soft greasy slate is what a minor likes when he is after gold, and in this claim it is to be found in abundance. In the No. 1 North Hidden Treasure gold has been found in an open cutting. This claim has been sold for £350. The Mountain Maid prospecting claim stand prominently forward as the richest mine on the Barrington. Gold was struck almost on the surface and has been followed down to ninety-four feet. The first two crushings were as follows:—83 tons, 7,328 ozs.; and 153 tons, 2,295 ozs. The next crushing after that a greater width of stone was taken and the result from 325 tons was 2,200 ozs., so that in round numbers about £24,000 worth of gold has been obtained from the reef in three crushings. There was scarcely a piece of quartz I saw that I did not see gold in the solid stone. The first two crushings were picked stone, the last crushing was not. Like nearly all the gold at Back Creek, that in the Mountain Maid claim contains about one-tenth part of silver.

This mill give you an idea of some of the best claims of this goldfield.—Yours, &c.,

1st December 1879.

—*North China Herald*, January. 22]

PREPARATION OF SAGO.—The Sago-palm (*Metroxylon sagus*) yields the principal food of the inhabitants of the islands, stretching along the western coast of Sumatra, who obtain the sago as follows :—The trees having been sawn into pieces four to five feet in length, each piece is split into four parts, which, after the bark has been removed, are placed in a shady place until dry, when the pith is rasped into a rough meal, transferred to a coarse cotton strainer, suspended over wooden trough, and kneaded into a smooth thin paste with water ; this kneading is continued as long as the milky liquid saturated with starch runs from the strainer. The contents of the trough are then allowed to settle, the supernatant water is removed, and the white sediment dried in the air.

MINERALOGY.

NEWS has been received at Rangoon by telegram from Akyab, that Messrs. Gillam & Co. have been successful in striking oil in the Boroogas. They had carried their boring down 27· feet when they came upon a large reservoir. The extent of the yield is not mentioned, but it is believed to be considerable. Hitherto the company were able to get a daily supply of between 170 and 180 gallons of oil, not thick like the ordinary crude mud oil, but much more liquid, and of the appearance of dark brown sherry.—*Englishman.*

A CORRESPONDENT at Ootacamund writes to a Madras contemporary :—"I told you in my last that a Mining Engineer has been sent out to relieve Mr. Severn, who proceeds immediately to England in view to select and bring out the requisite machinery and appliances for working the gold mines of Wynaad. Mr. Severn tells me he is exceedingly well pleased with his prospections in the Wynaad. He has commenced operations which will be continued during his absence by the Mining Engineer, Captain Poole. Mr. Severn has had much experience in the matter, having been employed both in New Zealand and Australia for over fourteen years, and is very sanguine that the gold mines of the Wynaad will ultimately prove remunerative speculations. Mr. Severn will return to India in June next. He is in raptures in regard to the Nadagany Valley gold reefs. A tunnel has already been ont, and the preliminary works in connection with his operations started."

FORESTRY.

FORESTS OF THE CAUCASUS.

REPORTING on the trade and commerce of the Caucasian Provinces, Acting Consul Lyall, after referring to the immense extent of forest-covered area existing in the Caucasus, points to the fact of their being of little or no commercial value. He says wherever means of transport to a market exists, either by rafting down a river or the vicinity of the sea-board, the forests have either been already denuded of good trees, or exorbitant prices are demanded for the right to fell. The mountains round Tiflis have for many years been completely cleared even of brushwood, and firewood is in consequence very dear. The practice of denuding the mountains, which goes on throughout the valley of the Kour, has resulted in either completely drying up, or diminishing seriously, the volume of water in the rivers. It may be expected, unless measures are taken for re-afforesting the mountains, or some scientific methods of irrigation introduced, that famines will before long take place.

The Government of the Caucasus have long had a complete reorganization of the existing Forest Department under consideration, but this reform, like many others just as urgently required, has hitherto been postponed *sine die.*—*John R. Jackson, Kew.*

TEA.

ACCOUNTS received from different parts of the district, both Hill and Terai, all concur in anticipating an early tea manufacturing season this year. It is, of course, full early yet to hazard an opinion as to when manufacture is likely to begin generally in the district ; as it is quite within the range of possibility that the temperature may drop suddenly this month for a few days or so, and if such should happen the result would be to throw the opening of the manufacturing season back a good deal.

THE letter we reproduce in another column from our Lahore contemporary explains a main disadvantage under which Indian tea suffers in the home markets. The writer's suggestion for a comparative trial of the two methods of packing tea deserves to be taken up, and we shall be very glad to know the results. A new reason for taking the greatest care in the preparation of Indian tea is the prospect of a competition between it and the China article, in Australasia.

THE DRYING OF INDIAN TEA.

HIMALAYAN writes to the Lahore paper as follows :—

A paragraph, in the *Pioneer* of the 4th instant, which says "an export on Indian teas states in a home paper that the chief drawback to their extended consumption in England, is the fact that they speedily deteriorate and will not keep," adding that " this is attributed to the insufficient drying of the leaf, or the use of machinery in the rolling process," is drawing attention. "Expert" is wrong so far as my experience goes, and is further likely to do the industry harm by his remarks.

With reference to the paragraph quoted here, I am very far from agreeing with " Expert" that Indian tea speedily deteriorates and will not keep; in fact, I assert that tea which is *panned* will keep, if properly packed in boxes lined with lead, for years, and instead of deteriorating will improve by keeping. Any one who knows anything of tea, will admit that tea is far more pleasant to drink after it is one or two years old, provided of course proper care is exercised in the factory in the packing and closing down of the lead. Had EXPERT attributed the cause of the tea he has found not to keep and deteriorate, to want of panning or bad packing, one could understand him. I know there are a few estates in the Kangra valley which do not pan, and I do not hesitate to say, that such tea, going home, is, on being opened and bulked in London, likely to lose both flavor and strength ; but tea manufactured as I have seen it (I do not speak here of leaf withered, rolled and dried by machinery), where care is taken with the withering of the leaf, the fermentation, panning, and final drying off, one may back to keep against China, Java, or Ceylon tea. Every broker knows, immediately on testing the tea, whether the withering or fermentation is defective, and if so the valuation of the broker would be depreciated immensely ; but then if the broker would explain the reason for his low valuation it would not be that the tea had deteriorated or would not keep. Of course, when tea is carelessly manufactured, and the day's tea thrown into the bins, or may be packed there and then in sheds and

despatched to the Calcutta auction, without being properly dried off over the charcoal fires, it must deteriorate in every way; but such cases are of rare occurrence.

Since the paragraph in the *Pioneer* to which I here allude appeared, I have had a long and exhaustive conversation with an experienced planter from the Kangra Valley, who entirely concurs with my views on the subject. This gentleman offers to prepare, as an experiment, 40 lbs. of tea, which he will pan and 40 lbs. which he will not pan, and pack both in cases lined with lead, ship to London, leave there for say two years or more, and have them brought back to Calcutta to be opened in the presence of three or more brokers there, who would report on both cases.

I recommend tea in lined lead boxes to families. The lid of the box should be carefully removed and a hole in the lead made just sufficient to admit the hand; take enough only out to fill the tea caddy, then press the lead down and close the lid, repeating this simple plan till the bottom of the box is reached, when it will be found that the last of the tea is equal in strength and aroma to the first cup. This is most necessary in damp weather. Next to this is tea packed in 1lb. foil packets and carefully covered with thickish paper. The objection to packets is that the tea gets broken, but that does not affect the quality of the tea. Tea packed in tin boxes is bad, because once the tin is opened there is no closing it down air-tight again, and the least damp getting to it deteriorates it in a very short time.

On many estates in Assam the sun does everything for the manufacture of tea. The article is neither panned nor fired, when they have sun enough to lay it on zinc sheets in the sun. Tea so treated will not keep. I further think that tea manufactured entirely by machinery is not up to that made or passed through the hand in every process.

GRADES AND QUALITIES OF INDIAN TEAS.

THE very varied and unnecessary assortments of teas sent forward from some gardens cause heavy expenses to owners, and undue trouble to the brokers and dealers.

Some invoices have no less than eight or nine different descriptions of teas, and some gardens still further lengthen their invoices by dividing all or some of these descriptions into breaks or divisions, differing only in value by a penny or so. We think managers should make up their invoices with as few grades as possible and limit them to the following kinds:—Pekoe, Broken Pekoe, Pekoe Souchong, and Broken Tea; or, in other words, two fine teas, one medium and one common tea. This plan has much to recommend its favourable attention on this side, and if the quality be good, competition will not only be secured, but entirely confined to these four kinds.

Too many gardens make what they consider fine teas, but which are, in reality, only very medium ones, the Pekoes from such gardens being inferior in cup to the Souchongs from the best gardens. There is generally an over-supply of medium teas on the market, and are therefore subject to much depression, more so than the finer or commoner grades, not only because of their abundance, but also to their close connection with good China teas.

Having confined his manufacture to the above four kinds, with a good marginal value between each, the planter should aim at making the quality of a distinctive character, and, even though it be a little peculiar, if it has any worth it will soon be discovered on this market. The following are the characters best liked in their order of merit:—1 strong, full, and pungent; 2, strong and fruity; 3, strong and malty; 4, pale, or light and pungent; 5, strong, and rather burnt. The make of leaf is quite a secondary matter; many an ugly-looking tea fetches a long price, owing to its wonderful liquor.—*Home and Colonial Mail.*

TEA MANURES.

ANALYTICAL experiments made on some samples of soil taken at various depths from tea gardens in Assam. The result of these experiments, which were made by Mr. Joseph Cripps, went to show that silicious matter very largely predominated, to the extent of 84 to 93 per cent.; while three very valuable forms of plant food—lime, potash, and phosphoric acid—existed only in very small, indeed in some cases, infinitesimal quantities. Turning to the constituent elements of the tea plant, it will be seen from careful analysis of tea-ash as made by Mr. Cripps, that the plant itself contains a very large proportion of the before-mentioned elements. The exact analysis is as follows:—

Potash	39·22
Soda	·65
Magnesia	6·47
Lime	4·24
Oxide of iron	4·38
Protoxide of manganese	1·08
Phosphoric acid	14·55
Chlorine	·81
Sulphuric acid	trace.
Silicate	4·85
Carbonic acid	24·30
	100·00

As Mr. Cripps forcibly observes on these data:—"The tea plant is one which extracts from the soil very large quantities of potash and phosphoric acid; and it is to the replacing of these constituents that the attention of the grower should be directed. It would appear that phosphoric acid and potash are most necessary for the full development of the tea plant, and, unless stores are developed from the subsoil, or their constituents are applied in the shape of manure, the soil will become exhausted, and disease of the plant a natural consequence of such exhaustion." The Odams Company's tea manure appears to have been prepared with a special regard to these facts, for, according to the independent analyses of no less than four eminent analysts—Dr. Voelcker, Mr. John Hughes, Dr. Macadam, and Mr. Cripps—it is very rich in all the elements which tea requires for its successful cultivation; and, therefore, specially suited for the soils of Indian tea gardens.—*Home and Colonial Mail*, December 19.

DECOMPOSED TEA.

MESSRS. J. C. SILLAR & CO., in a letter to the *Times*, direct attention to another case of adulteration in tea:—"In the year 1874 the steamer *Gordon Castle* was sunk near Lisbon, and after remaining under water for two or three weeks was raised, and 14,000 chests of her teas were sold in Lisbon at the rate of a third of a farthing per lb. The teas were in a state of fermentation, and condemned as quite unfit for human consumption. Notwithstanding this, they were redried and, had it not been for *The Times* calling attention to the matter, they would have been imported into this country, in all probability mixed with sound teas, and consumed long ago. We have now received information that this mass of impurity is being packed in empty tea boxes, which have been forwarded from London, and shipped from Lisbon at the rate of 100 half-chests per week. We have been unable to ascertain the final destination, but we hear that Hamburg is the place to which they are to be first sent. We have received a bag of the rubbish, and forward you a sample herewith. As you will observe, it has the appearance of coffee grounds, and the putrid smell having passed off, it will be difficult to detect when mixed with sound tea. It is to be regretted that the dealers here are what is called 'running for price,' and a heavy premium is thus held out to importers of common and adulterated teas. That the importation and mixture of such compounds with the food of the people will cause much sickness, we do not think there can be much doubt, and we trust that you will assist us in directing attention to the matter."

On this subject "Old China" writes to the *Times*:—"As a tea importer for upwards of 30 years, I can quite endorse Messrs. J. C. Sillar's remarks in their letter in your edition of last Saturday, and I think too much publicity cannot be given to the demoralised state into which the tea trade has fallen within the last few years, cheapness and not goodness being the *desideratum* to which all the energies of the dealers and retailers appear to be chiefly devoted. In years long gone by such was the demand for good tea that buyers in China, to obtain the finest quality, advanced beforehand to native hongs the principal part of the purchase money for the quantity required, with the object of securing as early as possible the finest and best well-known chops, to enable them to give the earliest despatch to the clipper ships, which they loaded at high rates of freight in order that their teas might arrive first on this market; but what we see in the present day is a premium and an encouragement given to the unscrupulous merchants, both native and foreign, to ship at a low cost anything resembling tea, only that its appearance is made so good as to deceive and cause it to be passed by the Customs. Within the last two months of November and December a very large quantity of such tea has been imported, and has been eagerly bought by the wholesale dealers at prices which have given the importer very large profits, while at the same time good pure tea, which could have been bought within 1*d.* per lb. of this trash, and really fine flavoury tea at 2*d.* per lb. above it, has been almost neglected. At the present time the little demand there is for good and fine tea is principally for export, the rubbish being retained in this country for the benefit of the working man and his belongings, and in a season too when he can ill afford to waste his money on a spurious article and who has been in the habit until lately of paying 2*s.* to 2*s.* 6*d.* per lb. for tea, which has cost the wholesale dealer not more than 11*d.* to 1*s.* 2*d.* duty paid. If you will continue your valuable support in exposing the nefarious practices of the trade and putting the public on their guard against the purchase of cheap and spurious tea, you will, I feel assured, be benefiting the poorer classes considerably, and may ultimately, I hope, induce the wholesale dealers to forsake the cheap and nasty and pay a little more for a good and pure article, which will alike be a pleasure and an advantage to the consumer."

TEA IN AMERICA.

CONTINUING our notice of the special report issued by the Government Printing Office of Washington on the subject of "Tea Culture as a Probable American Industry," the writer draws the attention of his countrymen to the adulterations of tea, enumerating the substances stated to have been found in tea, which are as follow:—Iron, plumbago, chalk, China clay, sand, Prussian blue, indigo, tumeric, starch, gypsum, catechu, gum, besides the leaves of the following trees: camelia, elm, chloranthus, willow, poplar, oak, elder, beech, hawthorn, and the wild plum. The writer might have added that this statement applies only to China tea. "It is generally understood," he continues—with the evident purpose of inducing his fellow-countrymen to undertake the cultivation of the tea plant—" that much of the manipula-

tion given to tea in Asiatic countries is directed toward fitting it for ocean voyages. For this transportation the leaves must be roasted before shipment, and thus the aroma developed by firing is largely dissipated before the tea is used. It is an old saying that the best teas are only to be had in their highest excellence in tea-growing countries, where they can be procured before they have been submitted to all the severity of the heroic processes which they have to undergo before being packed for long voyages in the holds of vessels. It may therefore be found that for home consumption only a less elaborate method of preparation may suffice, and that, as already mentioned, the article may enter into domestic commerce in cakes of dried leaves pressed into solid shapes, as is done with many other herbs, and the roasting which developes the aroma takes place immediately before use, as is now done with coffee. Probably it will ultimately be ground like coffee to secure the most delicate beverage." Our readers will, we think, be of opinion that this style of manufacture would not produce tea at all. He remarks :—"It will probably be many years before tea culture will engage the general attention of farmers and planters in this country. There are many reasons why this may be expected. The profits of the culture are not established ; the management of the plant and the proper application of the processes must be for many years of a purely experimental character ; and even where seemingly fair tests have been made failures will occur, and although these failures may be traced to causes which persistent effort would overcome, yet where there is outlay and loss, accompanied with some loss as to ultimate success, the effort will in most cases be abandoned."

Any attempt to estimate the profits of teaculture in America would, he says, " simply be futile ; this can only be reached after we see the results of actual and fairly conducted experiments."

It has been suggested that the United States Government could at a compartively small cost materially assist in determining the feasibility of tea culture and the solution of the question of profit. " What has already been accomplished by modern tea manufacturers in the way of improvements upon the older Asiatic methods only suggests that still further innovations may be possible."

"Seeing," he adds in conclusion, " that much of the care bestowed upon the manufacture of tea is merely for the purpose of meeting commercial exactions in regard to the appearance of the article, it may be that by ignoring mere appearance an equally good beverage may be produced by an entirely different system of preparation of the leaf. Of this I have," he says, " strong hopes."

" We procure the essential virtues of other herbs without subjecting them to such complicated processes, which, after all, are mainly to prevent the leaf from mouldering and decomposition; and there seems to be no valid reason why tea should differ from other herbs in this respect."

" To solve all doubts on the point, and to answer all questions," the writer of the report makes the following suggestion:—" For the Government to secure say 20 acres of land in a suitable locality, and plant a portion of it yearly with tea plants until ten or twelve acres of it are planted. Then when the plants have become sufficiently matured, provide a small laboratory fitted with the necessary apparatus, and place it in charge of a competent person, who would make such experiments in the preparation of the leaf as might be suggested. This service need not cost more than 20,000 or 25,000 dollars ; but it would require at least six years for its completion."

In an appendix, numerous extracts from letters submitted by cultivators of the tea plant are inserted, to show that the necessary soils and climates are to be found in America to suit the growth of the tea plant. Mr. Forster, writing from South Carolina, is evidently at issue with the author of the report on the method of preparing tea. He writes :—" The Chinese method of curing tea is impossible in this country, where we cannot obtain labour at five to ten cents. per day. Yet some equivalent to this process is necessary to the production of tea such as we drink it, for a decoction of the leaves dried without this manipulation has little resemblance to the beverage we all so much appreciate. I am convinced," he adds, " that the slow rolling and pressing at certain intervals and then the heating and rolling over and over before the final drying are required to break the sap vessels in the leaves in order to produce in the juices by contact with the air, a certain degree of fermentation necessary to bring out the flavour or develope the properties we find in the Chinese preparation."

A lady appears to have been the most successful planter hitherto among our Trans-atlantic cousins. Mrs. Screeven, whose address given as McIntosh, Liberty County, says of her mode of preparation :—" I have only prepared black tea, the process being very easy and simple. The leaves are gathered the day before they are to be dried, and spread thinly over tables to will (wither). The small leaves are cured by themselves as they make the most superior quality of tea. The day after being plucked, they are taken in the hands, and rubbed until they become soft and flaccid. They are then placed in heaps, and allowed to remain so for about one hour. They are then put into a Dutch oven which is heated by a few coals under it. While in the oven they are constantly stirred with the hand to prevent scorching. They are roasted five minutes, taken out and rolled again upon the table. After being rolled they are exposed in the open air, in the sun, and frequently stirred. While these are out in the air another set is in the oven. When all have been roasted, those first put out in the air are brought in, and roasted again for five minutes ; then taken out and rolled, again. They are now placed in a sieve about an inch thick and held over a few hot coals, stirring all the time. They are then taken out and rolled again. This process of rolling and toasting is continued until the tea assumes a dark colour. After all the leaves have been treated thus they are put in a basket and hung over a few coals, and frequently stirred until the tea appears black and dry."

After taking all these pains, the lady, we think, fairly deserves the credit which is given her of making " a good article for home use."

Another cultivator makes the somewhat startling statement that " half-a-dozen plants furnish my family of five or six persons with more tea than we can use." It is fortunate for him that he can add, " My plants have never suffered from insects of any kind," for on such a small estate " blight " might deprive him of his whole crop of tea.

It is evident that for some time to come India need not look for much rivalry from American tea, and we advise our friends on that side of the Atlantic to put their faith in pure Indian teas in preference both to the China teas with their adulterations and to the home-grown article.—*Home & Colonial Mail.*

COFFEE.

LEAF DISEASE IN NORTH COORG.

In this month of February, the trees on a coffee estate have the appearance of drooping, dejection, and languor; the late luxuriance of leaves have fallen pale and yellow on the dry red ground, and stripped of their load of purple-red berries, they little resemble the same trees of two months ago.

Pruning is being diligently pushed forward; and walking down the long rows of trees that the workers have lately been at work upon, shewing the trees in their most naked aspect, all superfluous wood removed, and the branches, that will give next year's crop, with but a few leaves toward the ends of their branches, the spikes of formation of the blossoms, but as yet visible on close examination, the ground strewed with the cut-off twigs, and a hot burning sun shining full on the over-parched grounds, gives but a poor description of the aspect of the trees as they now are; and if this is of the healthy and undiseased trees, what can be said of those that were attacked with leaf disease in November last. Then they became bare, excepting the unripe crop upon them which never came to maturity, and now they are but as a raised up heap of twigs without sap that break off with a sharp report as the hand is passed roughly through them.

At present this disease has not attacked the more fertile estates lying in South Coorg. It is to the north and west where it is most apparent, and although it is spreading through the medium of abandoned estates, and neglected native holding no extraordinary precautious have been taken to stop its progress. By extracts from the Madras papers, and through the courtesy of a friend who forwarded the published report, as issued from the *Ceylon Observer* office, I read of Mr. Morris's active and learned investigations regarding this disease (the Hem. Vastatrix) and of his many and practical attempts to stop its further advancement, and at the same time to restore the sick trees to health again by means of different manures, acting as a medicine and skilfully applied. All this was then eagerly discussed, and several copies of this pamphlet were sent home to England to some of the proprietors resident there, and interested in this part of Coorg. Notwithstanding the very large cost of importing the flowers of sulphur, and the bringing up from Mysore (distant 80 miles) of large quantities of lime, orders were about to be issued, when there quickly appeared different paragraphs shewing how these medicines did not act on the diseased trees as had been hoped, and thus leaving the question in abeyance, and the orders were not sent.

Some planters have a firm belief that this disease will disappear as mysteriously as it came, now seven years ago, in proof of which instance is made of the attack of bugs, or black insects which many years ago infested every coffee tree doing great damage and mischief, and after stopping one season and a half then disappeared, not to come again.

It has lately been remarked by a correspondent in the *Indian Agriculturist* that under living or forest shade, the trees are more healthy, and are less liable to sickness than those exposed in the open; but trees so grown seldom give one-tenth of the crop, that a healthy tree without shade would annually bear: and in certain localities shade is really dangerous to the coffee trees growing beneath.

Some forest land that was bought many years ago (when the delays and hindrances of to-day were not known,) was about to be felled last December; then the subject was mooted of how to commence, whether to fell straightway and afterwards to burn; or to mark and carefully fell only those trees that would not be needed for shade, and afterwards have small fires to clear away the under growth, &c.

With very little discussion the first plan was decided on for the enormous drip-drip of above two hundred inches of rain, would be ruinous alike to the trees and to the newly disturbed soil.

There is an example in an estate a short distance away, that was planted under forest shade or trees now six years ago; the stems are thin, the branches are long; and the crop very, very small; the shade may be too thick, and the drip from the lofty trees too heavy for the coffee plants to thrive under, for many die; any how, it is decided by the owners of the two clearings that make the total for many miles around Mercara, to ignore the natural shade, and trust to science for the future to clear away the mystery of Hem-Vastatrix.—*Madras Standard.*

THE CROP OF 1879 IN THE THREE GREAT COFFEE COUNTRIES OF THE WORLD.

Taking it for granted that Messrs. Patry & Pastour's figures are close to the truth, it would appear that, in the year recently closed, Brazil went beyond all previous experience in her export of coffee. Up to a few years ago the accepted figures for the total production of the great South American Empire were 260,000 tons, of which 200,000 in round numbers were exported, leaving the odd 60,060 for internal consumption. In 1879 the quantity exported far exceedeed the previous figures for total production, thus:—

Rio	208,000 tons
Santos	70,600 ,,
TOTAL	278,600 ,,

Adding the usual 60,000 tons for home consumption, we get a total production for Brazil as shewn below:—

Exported	278,600 tons.
Consumed	60,000 ,,
TOTAL	338,600 ,,

or a third of a million of tons, equal to 6,672,000 cwts.! In the face of such figures, the only wonder is that prices have not gone lower. The safety-valve has been the United States market, and we in Ceylon have special reasons for wishing that prosperity in the Union may continue and increase. Beyond the astonishing figures for 1879, it seems impossible that Brazil can go. Her land resources are ample, but the labour difficulty will daily become greater.

Java (and Sumatra) did not, like Brazil, shew her culminating crop in 1879, but it was only 6,000 tons under the round 100,000 tons. Local consumption we have not figures for, but, probably, it may bring the figures for total production up 180,000 tons. The population is about twice that of Brazil, but we suspect the vast mass of the Javanese never taste coffee, unless in the shape of a decoction of the leaves. Ceylon, alas! shews decadence of a marked character, but the quality of her produce is still high. Local consumption is so restricted that we do not suppose a higher figure than 45,000 tons should be used to represent the total production of Ceylon in 1879. Taking the figures as indicated, we get for the three great coffee countries of the world for 1879:—

	Exported.	Consumed.	Total Production.
	Tons.	*Tons.*	*Tons.*
Brazil	278,600	60,000	338,600
Java (and) Sumatra ...	94,000	86,000 (?)	180,000
Ceylon	41,200	3,800 (?)	45,000
Total	408,800	99,800	508,600

For all the other coffee countries of the world, our estimate, as given in the last edition of our Hand-book, is less than half the above. If it is near the truth we get for

	Exported.	Locally Consumed.	Total Production.
	Tons.	*Tons.*	*Tons.*
Minor coffee countries ...	173,500	75,050	248,550
Add three great countries	408,800	99,800	508,600
Coffee production of the world	582,300	174,850	757,150

This gives the total production of coffee in the world at over three-quarters of a million tons, or say in cwts 15,143,000. About a dozen years ago, our calculations led us to adopt 13,000,000 cwt. as about the quantity, and after very extensive inquiries and the examination of all the official, consular, and general publications within our reach during 1876-78, the following were the estimates we arrived at as embodied in our last Hand-book:—

THE WORLD'S PRODUCTION OF COFFEE.

Countries.	Estimated Area under cultivation. Acres.	Present Max. Export of Coffee. Tons.	Estimated Local Consumption. Tons.	Total Max. Production. Tons.
Brazil (including exports from Rio, Santos, Bahia, Pernambuco, and Ceara)	1,500,000a	240,000j.	60,000b	300,000
Java and Sumatra	1,200,000c	90,000j	20,000	110,000
Ceylon	263,000	50,000j	5,000	55,000
India	150,000	25,000j.	7,000	32,000
Central America (between United States and Venezuela) d	210,000	40,000d	5,000	45,000
Venezuela e, Peru, Bolivia & Guianas	220,000	40,000	8,000	48,000
Hayti or San Domingo ...	200,000	28,000	7,000	35,000
Cuba & Porto Rico	180,000	17,000	8,000	25,000
West Indies f	40,000	5,300f	3,500	8,800
Arabia, Madagascar, Mauritius, Reunion, Abyssinia, Mozambique, and North-East Coast of Africa ...	220,000h	7,500	22,500g	30,000
Natal	800	50	50	100
Liberia and West Coast from Loanda to Cape de Verde Islands, including Lagos, Siera Leone, Gambia, Gold Coast, Elmina, St. Thomas St. Helena, &c., &c. ...	100,000h	4,500	10,000	14,500
Manilla, Celebes i, and rest of Eastern Archipelago and Australia	45,000	5,000	3,000	8,000
Sandwich Islands and rest of Pacific Isles, including Fiji and New Caledonia ...	12,500	1,200	1,000	2,200
Total ...	4,291,800	553,550	160,050	713,600

a This area includes old and young coffee. It must be remembered that the style of cultivation and number of trees per acre differ greatly in different countries; for instance in Brazil each tree bears far more than in Ceylon, although the number per acre (from 300 to 500 being much less than in Ceylon (1,200 to 1,400) and the cultivation being less systematically attended to, the rates of production per acre do not show so much difference. According to Mr. Scott Blacklaw, coffee in Brazil bears at the rate of 10 cwts an acre, but this is in the exceptional cases where regularly planted.

b Including the consumption in the adjacent States of South America.

c Mr. Abbay estimated that 19-20ths of the Government Coffee land in Java yielded only 1 cwt an acre.

The value of the world's production of coffee (over 14 million cwts.) would be about 50 millions pounds sterling in the wholesale markets.

d Including exports of New Grenada (Savanella and Maracaibo) 90,000 cwts; Costa Rica 340,000; Nicaragua 45,000; Salvador 120,000; Guatemala 290,000; Southern ports of Mexico 85,000 cwts.

e Including districts of Laguayra, Porto Cabello, Ciudad, Bolivar, &c.

f Including exports from Jamaica 3,500 tons; Trinidad 50; Dominica 250; and French Colonies Martinique, Guadeloupe, Cayenne, and other small islands, Bermuda, Grenada, St. Lucia, &c., 1,500.

g Including consumption in Syria and Turkey of Arabian coffee.

h Including wild or indigenous coffee.

i Celebes is said to produce 25,000 cwts from 3 500 acres.

j Brazil crop in 1874-5; Java 1876; Ceylon 1869-70, and 1872-73; India 1871-72.

THE WORLD'S CONSUMPTION OF COFFEE.

OUR calculation of the World's Consumption (usual not maximum) is as follows :—

	Tons.
Continent of Europe	300,000
United States and Canada	110,000a
Mexico, Central America, and the West Indian Islands	28,000
Brazil and the rest of South America ...	86,500
Asia including Java and the Eastern Archipelago...	76,000
Africa b	35,000
United Kingdom	15,000
Australasia and Pacific Isles	6,000
Tons ...	686,500

This is the average in a year of abundant production. In 1820, the world's consumption of coffee was not more than 150,000 tons.

It will be seen that, while Ceylon has fallen off in production, Brazil and Java have given crops above our maximum estimates. Looking at the enormous advance of Brazil, even if we suppose that a good deal of the crop of 1878 was exported in 1879, it seems pretty clear that 15,000,000 cwts., now closely represent the quantity of coffee produced and consumed in the whole world. Ceylon at present scarcely ranks for one-fifteenth of this quantity, but then nearly all the produce is exported, and we hope that export will yet be largely increased. The taste for coffee is so widespread and is increasing so rapidly that there seems little fear of glutting the market, especially looking at the manner in which the enormous Brazil crop has been disposed of. Pretty soon "Ceylon Liberian coffee" will be figuring in consuming markets, and by the time the railway to Nanu-oya is completed, we trusted the Arabian bean will have shaken off the incubus which has weighed it down in the past decade, and that Ceylon will come in as a far better third than she now does.—*Ceylon Observer.*

CINCHONA.

THE YIELD OF CINCHONA BARK.

THE utmost diversity prevails in the experience gained by cinchona planters in Ceylon of the yield of bark per tree in respect of both the crown and yellow description. That different districts and varying altitudes should give different results was to be expected, but even in the same district and under somewhat similar circumstances we have been surprised to learn how great has been the discrepancy between the returns got from trees of nearly the same age. It is evident that the proper age for stripping bark will vary considerably at different altitudes and nothing but the collection and comparison of the available experience throughout the country, can enable fair and reliable deductions to be made for the guidance of both planters and merchants. There is no doubt that valuable property is lost if not destroyed through premature coppicing and stripping, and yet on the other hand we have reason to believe that in some instances trees are left too long to secure the fullest advantage from their crop of bark. A planter at a high elevation the other day informed us that he meant to cut down a large number of officinalis trees, five years old, to satisfy financial demands in this year of depression, but on experimenting with a few trees he found that instead of three-fourths of a pound of dry bark per tree as he had hoped for, the return was not likely to average much more than one-fourth pound per tree. Now in such a case it is very probable, considering the altitude, that the growth of two more years would double, if not treble the average crop of bark. Lower down the case is very different. "What do you think, "—writes a Kelebokka correspondent to-day —"of 7¾lb. dry crown bark from a 5½-year old tree (large-leaved variety)?" We can only say that we suppose this return is the maximum yet experienced in Ceylon of crown bark for the age mentioned. Our correspondent should have said whether root bark was included. We suppose not. The largest return of red bark reported to us was that obtained by Mr. Chippindall from an old tree in the Nilamber district which made up—with roots, stem, and branch bark—the grand total of 60lb. when dry, but we have since heard of three trees on Durrawella estate, Dikoya, yielding an average of 62lb. each, and of another tree on New Forest cut for the third time, the total of three crops including root bark being over 60lb.! In Dilosbagie, Mr. Blackett not long ago cut down a thirteen-year old tree from which he got, we believe, 28lb. dry bark. It is only by bringing together such varied experience that reliable data can be framed as to the prospects and value of cinchona cultivation in different districts. The large number in our planting and mercantile community who are interested in this important industry, will therefore, be glad to learn that in connection with the preparation of a "Ceylon Cinchona Planters' Manual" (which has been placed in competent hands) we have arranged to have all the valuable information in the *Observer* files and directories collated and a circular issued to obtain the results of experience gained in different districts in regard to a number of doubtful and interesting points.—*Ceylon Observer.*

a What tea is to England coffee is to the United States, more especially in the Southern States; the consumption has increased from 80 million lb. in 1868 to 116 millions in 1871, but high prices and reduced production as well as adulteration have stopped this continuous increase latterly.

b Cape Colony has imported from Rio as much as 60,000 cwts of coffee in one year. Algeria at the other end of the Continent also imports 60,000 cwts.

RENEWING OR COPPICING CINCHONA.

THE suggestion made in a communication by a correspondent in our present issue, in regard to experiments on the renewing system by means of cattle manure, instead of moss, will we hope be tried on a small scale. There has never been, we believe, any doubt as to the superior advantage of the renewing system over that of coppicing; and if it be found that the substitute for moss recommended by our correspondent is equally efficacious, a great part of the difficulty will be overcome. The removal of the bark from a standing tree in alternate longitudinal slips, is a task involving no doubt more trouble, care, and time, than the stripping of bark from felled trees, but in the case of the experiments which are recommended, it will be sufficient that the planter carries out the process on such a number of trees as he may be able to bark with his own hands: should it be found successful, there need be no difficulty in training careful labourers to perform the work on a larger scale hereafter. The question to be determined by the process suggested is of course, not merely to promote the formation of bark, but to assist in the deposit of the alkaloid within it, and although the bark may be rapidly restored, as related by our correspondent, it will still remain to be seen what period is required for the formation of the only alkaloid whose presence alone can give it market value. There is no reason that we can see why the substance recommended should not aid in the formation of these substances as rapidly and as effectually as moss. The experiment is, however, well worth the trial, and it must be left to time to demonstrate the results. There is no doubt much yet to to be learnt in regard to the growth of cinchona as a profitable investment, and naturally as the supply of the article increases, and the market value declines, which must inevitably be the case, the inducement to effect improvements in our mode of culture will become stronger from the very force of competition. We have yet to learn the comparative effect of various soils and altitudes, and modes of cultivation on the formation of alkaloids, as well as the nature of manures to be applied, and looking to the fact of the age at which trees are most productive, all this knowledge can only be acquired by a long course of patient and careful investigation. For some time to come there will no doubt, be a good deal of hasty cropping in order to take advantage of the present favourable state of the cinchona market, but as larger supplies go forward there will be less inducement to rush this produce for shipment, and thus time will be allowed for the accumulation of useful facts. If planters will take the trouble to keep a record of experiments and their results, a valuable mass of information will be accumulated that may in the end be turned to good account.—*Ceylon Times.*

PROGRESS OF CINCHONA CULTIVATION.

NOT many years ago the world was dependent for its supply of the most valuable tonic and febrifuge medicines ever discovered, on certain naturally inaccessible and politically disturbed regions of South America, where, at elevations varying from four thousands to eleven thousand feet above sea level, the various species of cinchona trees grow wild. When quinine, first extracted from cinchona bark in 1820, began to be recognised as a prime necessity of healthy life in many quarters of the globe, the utter disregard of future requirements shown by the native bark collectors in their wanton destruction of the cinchona forests gave rise to fears that the supply of bark might eventually cease, and forced European communities to consider the practicability of transplanting the cinchona from the western slopes of the Andes to other and more accessible regions fitted by soil and climate to receive it. For its proper development, the necessary elevation, with a moist atmosphere and an equable temperature equally removed from frost and from excessive heat, were indispensable, and these the Dutch and English Governments were advised would probably be found in certain portions of their extensive tropical possessions, where the need of an efficient febrifuge was specially felt, the Indian Government at that time (1852) spending no less than £30,000 annually in the purchase of quinine and bark. The initiative in this important experiment in acclimatisation was taken by the Dutch, who in the forest-clad mountains of Java found the requisite conditions for cinchona cultivation; and although for many years they were unsuccessful, owing to want of practical knowledge, and to the fact that the species obtained from South America proved

deficient in quinine-producing quality, they have at length overcome their chief difficulties, and Java now exports a considerable quantity of exceedingly rich bark, one of the best quinine-yielding species having been found to thrive there better probably than anywhere else out of South America. In order to obtain plants of the various species of cinchona most valued for their bark, the Indian Government sent an expedition, under the leadership of Clements R. Markham, which penetrated the dense forests of New Granada, Ecuador, Bolivia, and Peru, and after encountering the greatest difficulties and privations, owing greatly to native jealousy of its objects, returned to India with a stock of plants and seeds, greatly reduced through shipwreck in the Red Sea, but sufficient to start the plantations which are now beginning to yield a yearly increasing harvest of bark. The chief plantations are on the Nilgiri Hills, the most salubrious region in India, in British Sikkim, in the Himalaya slopes, and in Ceylon. In Dr. King's recently issued report for 1878-79 on the Government cinchona plantations in Sikkim, it appears that the number of the trees there planted out amount to more than four millions from which during the same year 264,000lb. of bark had been taken, while the number of trees in the Nilgiri Government plantations is probably not much less. In Ceylon and in the Wynaad, on the other hand, cinchona cultivation is carried on vigorously by private enterprise, the Government gardens being devoted to the propagation of plants and the raising of seedlings. According to a recent writer in the *Pharmaceutical Journal*, there are not fewer than seven millions of cinchona trees planted out in Ceylon. So familiar, indeed, have they become, both to natives and colonists, that, according to the same writer they are now looked upon as indigenous, and the natives, having now the fullest confidence in their remedial properties, "do not hesitate to help themselves to a strip of bark from the nearest tree when occasion necessitates it." Unfortunately the species which thrives best in India, and which is fast superseding all others, is the red cinchona bark—a native of the western slopes of Chimborazo—which contains a smaller proportion of quinine than most of the other species. Quinine, however, is only one of the alkaloids extracted from cinchona bark; quinidine, cinchonidine, and cinchonine being others. These have hitherto been regarded too much in the light of waste products. The Madras Cinchona Commission, however, after experimenting on the comparative values of these four alkaloids as febrifuges, came to the conclusion, which more recent experiments have confirmed, that quinine and quinidine are of equal value in this respect, while cinchonidine is only slightly less efficacious, and cinchonine, though inferior to others, yet possesses sufficient febrifugic virtue to render it highly serviceable as a substitute for more expensive preparations. The Red Cinchona bark which promises to replace all other species in India—3½ millions out of the 4 millions of trees in the Sikkim plantations belonging to it—is specially rich in cinchonidine. The discovery of remarkable febrifugal properties in all the cinchona alkaloids has led the Indian Government to prepare a cheap medicine for the use of the fever-stricken native population, the majority of whom have hitherto been without a remedy for their frequent agues owing to the high price of quinine. The new medicine is known as "Cinchona febrifuge," and consists of the alkaloids extracted as a whole. Considerable prejudice existed for some time against this compound, owing, it was said, to the fact that it produced nausea similar to that caused by an overdose of quinine; this effect, however, was proved to have been due to overdosing with "febrifuge," on the supposition that it was weaker than quinine. Taken in equal doses with the latter, it is quite as efficient and not more nauseous. The growing popularity of the Government febrifuge is seen in the increased demand for it. Thus in the year [illegible] the turn out of the medicine was only 49lb, in 1875-76 it had increased to 1,040lb., and last year, according to Dr. King's report, it had risen to [illegible]lb. It now costs about one shilling and ninepence an ounce. Strenuous efforts have of late been made to bring into use in this country the sulphate of cinchonidine as a cheap substitute (two shillings an ounce) for the expensive sulphate of quinine, but although it is believed by medical men who have used it to answer as well as quinine it has not yet overcome the suspicion which always attaches to new and cheap drugs.

It was feared that the cinchonas removed from their native forests and brought under cultivation would yield less of the febrifugal alkaloids than when in a state of Nature. The opposite, however, has been the result, all the leading species seeming to improve in this respect under cultivation. Still more remarkable was the discovery made by the late Mr. M'Ivor, chief of the Nilgiri plantations, that the cinchona could be made to yield a still greater amount of alkaloid by simply protecting its bark from the action of sunlight. Exposed to light, the bark was observed to have a tendency to redden, the colouring matter being supposed to be produced at the expense of the alkaloids, and Mr. M'Ivor found that, by covering up the stems of his plants with moss, he could double and even triple the productiveness of the bark. In South America it has been the invariable practice to cut down the tree in order the more readily to denude it of bark, but in the Indian cinchona plantations, this wasteful process has been proved to be unnecessary, the trees there being made to yield successive crops of bark by taking off longitudinal strips from top to bottom in successive years, and covering over the naked portion with moss, when a renewal of bark takes place. This method has been attended with success in the Nilgiri plantations. Owing however to the presence of ants which, getting beneath the moss, eat the young bark as quickly as it is formed, this highly economical method is not available for the Sikkim cinchonas. Another method largely adopted in India and Ceylon is that known as "coppicing," in which the tree being cut down almost to the ground, a crop of shoots is given off from the still vigorous roots which in the course of a few years yield a valuable bark. Up-rooting is also practised enabling the cultivator to obtain the root bark, which is the part containing the largest proportion of alkaloid, this proportion diminishing, it is said, as we ascend the stem. Owing to the wreckless manner in which the bark-peelers of the Andes have conducted their operation they have gone far to kill the goose which for about two centuries has laid for them the golden egg. Thus of yellow cinchona the richest of all the barks, little is now obtained from its native forests of Bolivia and Peru, our supplies being chiefly drawn from Java and India. Considerable quantities of what are known in commerce as Columbian and Carthegena barks are exported from New Grenada and are employed exclusively in the preparation of quinine. That the importance of this source of quinine is still considerable, was shown in the great increase a few years ago in the price of this alkaloid due to civil war in New Grenada and Columbia which for a time at least, almost, annihilated the trade. That the closing of this source of supply was not more severely felt, was entirely due to the large imports of bark from Java and India. The wealthy landed proprietors in the cinchona States of South America are beginning to realise the necessity of fostering, if they would not lose this source of wealth, and should they begin to plant where hitherto they have only reaped, they might easily retain their hold on the markets of the world. Cinchona culture has been attempted in many parts of the United States, but even in California, where the conditions are most favourable, it has not yet succeeded. Better success, however, has attended its introduction into Jamaica, where, during the last ten years, cinchona plantations have been gradually extending. Jamaica bark is now in the market, and a parcel of it sold in London in September last, fetched 2s. 10d. per pound, "being a higher price," says Sir J. Hooker, in his recent report on Kew Gardens, "than was reached by either East Indian or Ceylon bark sold at the same time."—*Graphic* [illegible].

SILK.

THE Government of the Punjab is evincing considerable interest in the silk industry. An exhibition of silk cocoons was held at Nurpur on 25th April 1879, and a report on the subject, with others of the same nature, has just been issued. The number of exhibitors was 30[illegible] as against [illegible] in the previous year, and the quantity exhibited 70 maunds 20 seers, against 33 maunds and 11 seers at the previous meeting. The sum of Rs. [illegible] was distributed in rewards, and the general impression of the committee was that the industry was steadily gaining ground in the estimation of the people. Extensive plantation of mulberry trees have been laid out, and an experiment tried with the castor-oil plant on the leaves of which certain silk worms feed; but this turned out a failure, the plant not having sufficient strength to resist the Punjab winter. For this variety of worm, it is proposed to cultivate the castor-oil plant afresh every year, in certain suitable localities. One great difficulty in that district is the effect of the periodical hot winds, which is to destroy large numbers of the worms. There seems all the greater reason why the castor-oil leaf-feeding variety of worm should be attended to, as it has been found that it is not so much affected by the hot winds. An English firm has sent an agent with a liberal credit, to commence operations on a large scale, and by means of advances in money and eggs, to encourage the industry among the natives, the firm undertaking to purchase the entire produce for cash. This may tend to develop this useful and eminently suitable industry among the natives of the Punjab.

TOBACCO.

TOBACCO STATISTICS.

THE last number of the *Imperial Statistics of Germany* compares the taxation of the chief nations of the world in respect to tobacco. Of the countries where the sale is a Government monopoly, France last year stood first, the gross duty, with profits, amounting to 7s. 1½d. per head of the population annually, the net revenue from the article being 5s. 8¼d. per head. In Austria the gross was 5s. 5¾d., the net, 3s. 5d., in Hungary, the gross 3s. 3½d., the net 1s. 7d. in Italy, the gross 3s. 11d., and the net 2s. 8½d. In Great Britain, the duty and licences brought in 4s. 10¾d. per head of the population for the year, and in the United States 4s. 4½d. In Germany, on the

other hand, where the duty was very light, the average was no more than 7¾d. per head of the population. The new tariff which has been passed this year will make the next return for Germany much heavier. The value of the tobacco consumed in Germany in 1878 is calculated to have been 353 million marks, or £17,650,000 sterling, the total return to the revenue being 26,383,966 marks, or £1,319,198. The quantity consumed in that empire in the year is stated at 2,196,000 cwt., or rather more than 100,000 tons. Of this quantity 589,600 cwt., or upwards of 29,000 tons, were consumed in the form of cigars. Reckoning a hundred cigars to a pound in weight, the number of cigars consumed in Germany in 1878 would be upwards of seven milliards, which would give two cigars a day all the year round to ten million smokers. But besides cigars the Germans smoked in the year 1,327,200 cwt., or upwards of 60,000 tons of tobacco more or less manufactured. In the form of snuff they took 160,600 cwt., or 8,000 tons in the course of the year, while in the way of chewing tobacco they limited themselves to the moderate quantity of 14,200 cwt, or about 700 tons. Rather more than one-third of the total weight of tobacco consumed was grown within the limits of Germany, the quantity so produced in 1878 being 5 [illegible] cwt., while the imports amounted to 1,768,855 cwt. of [illegible] leaves 4,827 cwt. of roll tobacco, 14,870 cwt. of cigars [illegible] of stems for snuff, 513 cwt of snuff, and 801 cwt of chewing tobacco. The total area of land engaged in growing the plant in 1878 was 10,016 hectares, or about [illegible],520 acres. Two-thirds of the quantity was grown in Rhenish Bavaria, Baden, South Hesse, and Alsace-Lorraine, in which districts [illegible]1,623 hectares were employed in the cultivation of the plant.

TOBACCO IN BIJNOR.

BIJNOR has witnessed several interesting [illegible] in the growth of tobacco, and as the subject has not yet been [illegible] treated in any part of the Gazetteer notices, the cultivation of [illegible] Indian weed deserves some special notice. [illegible] is not one of the principal crops of the district, and indeed the area over which it is sown [illegible] its usually to less than [illegible] acres [illegible] year. Of [illegible] [illegible] by the sites of abandoned cattle [illegible] on the edge of the [illegible] and the remainder [illegible] village homesteads, or in [illegible] the low alluvial [illegible] In the two [illegible] with manure, where [illegible] peculiar [illegible] and in order [illegible] Former [illegible] [illegible] it is grown [illegible] however, have [illegible] as well as a [illegible] enough [illegible] to be strong, and enough [illegible] As, moreover, the crop is an exhausting one, it must never and is never grown on the same land for two years running. It requires the most careful manipulation and tending, and hence the Sani clan, most painstaking of husbandmen, are the only cultivators who manage to bring it to perfection. The native tobacco grown [illegible] district is of three varieties. The *Alwarya*, first introduced [illegible] from the Native State of Alwar, has short, broad crumpled [illegible] grew [illegible] *Baingan* on the other hand, [illegible] long thick smooth leaves [illegible] resembling those of the egg-plant [illegible] from which [illegible] its name. Lastly the *Desi* or common [illegible] tobacco, has long, narrow pointed leaves, not unlike those of the Virginian variety. The poorer classes prefer to smoke *desi* tobacco on account of its cheapness but the two first mentioned kinds fetch in the market a price fully 2[illegible] per cent higher. Tobacco is propagated by seed sown in nursery beds during November and December. As the seed is minute, and resembles the earth in color, it is mixed with ashes or white sand, to enable the sower to see that he is not scattering it too thickly. During their stay in the nursery bed, the seedlings must be well protected from wind and frost; and when removed hence (in the latter part of January or February, if the season be exceptionally cold), they have usually attained a height of about 2 inches. The beds in which the young shoots are now planted, 6 or 9 inches apart, are about 6 feet square and have been ploughed four times, as well as throughly cleaned. These beds are flooded once every third day, and the appearance of a weed is the signal for its destruction," but more trouble is experienced in extirpating a nicotine-loving worm which sometimes attacks the roots of the crop.* From the middle of May to the middle of June the mottling of its leaves announce the approaching maturity of the plant; and when those leaves break crisply if bent, it is considered ready for cutting. The crop is now cut down the whole at once, and left to lie out all night as it fell; no attempt is made to sort the foliage, and indeed no distinctive names for the variously placed leaves exist. In the morning when the leaves, limp and pliable from the dew, are in no further danger of breaking under handling, the crop is gathered up and carried to some smooth spot, generally beneath the shade of a tree. Here they are piled together in fermenting heaps of about a cubic yard in size, the leaves pointing inwards towards the centre, the stalks outwards; and the process of natural fermentation begins. No attention is paid as elsewhere to the drying of the "mid-rib" before fermentation, nor are the leaves artificially damped during that process. But the plants are frequently turned over in the heap, to make fermentation as general and equal as possible, and care is taken to avoid over-fermentation which burns and blackens the leaves. When the process has sufficiently advanced, the heaps are opened out and allowed to cool; and when the leaves are sufficiently dry to be put together without risk of further fermentation, the stalks are plit into four and tied with the leaves int small bundles. The tobacco is, now ready for market. No time for mellowing before sale is given, or indeed required; for native tobacco is meant, not to be smoked by itself, but merely to form the basis of a smoking mixture in which sugar, spices and other foreign elements are largely represented. From the roots left in the ground after reaping, springs a scanty second crop; but this is too worthless to repay the care of the Sani, who leaves it to be gathered by the cow-herds, or trodden under foot by their cattle.

Experiments in the growth of foreign tobaccos have been carried sufficiently far to show, that were this cultivation sustained by professional planters, the district would be enriched with another source of wealth, and perhaps, another valuable industry. There was apparently no difficulty in finding a profitable market for what was produced; but the producers were amateurs with other work to absorb their attention, and other means of livelihood. In 1868-69 some land in the Bijnor forests belonging to Colonel Parrott and Major Smith, both of the Stud Department, was sown with seven varieties of tobacco, viz., (1) Virginia, (2) Kentucky, (3) Connecticut, (4) Havanna (5) Manilla, (6) Latakia, and (7) Bhilsa. The seed of the first three was procured from America direct, of the 4th through England, of the 5th and 6th through Calcutta, and of the 7th from Delhi. The Connecticut and Bhilsa growths may be at once dismissed from this narrative, as the latter was a complete failure, and the former, of which nothing is heard, was presumably not a success. By far the most successful in every way was the Virginia, which throve vigorously. Its leaves grew from 2¼ to 3 feet long and from [illegible] to 1¼ foot wide at their broadest part, while its stalks were [illegible] inches in diameter. But its quality was proportionate to its quantity. The tobacco it produced was well flavoured and strong, being on the latter account highly appreciated by natives. It was grown for two years from imported seed, and the plants thus propagated, themselves yielded seed from which in the 3rd year a crop by no means degenerate was raised. The Kentucky plant, which resembled in appearance the indigenous *Baingani*, produced a coarse and strong tobacco much fancied by natives, but as a small quantity only of its seed had been obtained it was not grown for more than one season. The same cause prevented the prolonged cultivation of the Latakia plant, which, however, yielded as long as it lasted fair quantities of well flavoured tobacco. Neither Havanna nor Manilla plants appear to have thriven, and it is probable that the coldness of the winter climate, and perhaps the soil also, disagreed with them. From both a small supply of fair tobacco was obtained, but the flavour of the latter brand was too mild to satisfy the native taste. The system of tillage adopted for the foreign, was much as that for the native tobaccos, the only difference being that when transplanted from the nursery beds, the young seedlings were placed more widely apart, at intervals of at least three feet. [illegible] plants were moreover, dressed, only 6 or 8 of the most promising [illegible] being allowed to remain on each. Sowings were in one year [illegible] as early as August, when the transplantation was effected in October [illegible], entirely resulted in failure, and about three-quarters only of the crop [illegible] realized. For the preparation of the tobacco, drying sheds [illegible] approved principle were erected, from which sunshine was [illegible] excluded. Great care was bestowed on every stage of the manufacture. A sailor from Cuba, who had once worked on a tobacco plantation on that island, was induced to exchange the longshore fascinations of Calcutta for the less hospitable wilds of Bijnor, and the arrangements were placed under his charge. But some secrets of the curing process adopted he obstinately refused to divulge. A smoking mixture manufactured at Bhogpur out of Virginia mixed with Manilla and flavoured with Latakia, was sold in tins to European purchasers, and obtained for the three some [illegible] brity. But the growth and manufacture of these tobaccos was not energetically sustained, and a promising experiment was gradually abandoned. Mr. Markham estimates the cost of producing native tobacco at Rs. 81, and the returns at Rs. 144 per acre, the net profit being therefore Rs. 60. The average outturn per acre he gives as 3,837 5/7lb. avoirdupois, and the average price per 92 5/7lb. as Rs. 4. For the European tobaccos larger figures must everywhere be substituted. Even the dried stalks and midribs fetched as large a price as ordinary native tobacco, while the refuse leaves rejected by the curer sold for 2¼ times as much.—*Delhi Gazette.*

* Settlement report paras, 179-80. All Mr. Markham could ascertain about the name and characteristics of this worm was that it is *Kire-ki Kism* a kind of creeping thing. The omnivorous white ant leaves the tobacco plant unmolested.

ADVERTISEMENTS.

APPLICATIONS

For the lease or disposal of the Government Tobacco and Experimental Farm at Myoung Toung at Akyab District, will be received by the undersigned.

THE Farm is on the Kaladan river, about 75 miles from Akyab, with which place there is weekly communication by steam launch. There are good out-buildings, and about 50 acres of cultivated ground waste land suitable for Tobacco, Tea, Rice, &c., is at once available for the extension of the farm, and may be granted on special terms under the sanction of the Chief Commissioner of British Burmah.

G. J. S. HODGKINSON,

Officiating Commissioner of Arakan.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

CORRESPONDENCE.

THE MIDDLEMAN IN TRADE.

TO THE EDITOR.

SIR,—The co-operative movement at home points to the existence of a system, which it is intended to supersede; I mean the interference of the middleman. He is doubtless a necessity, and it is not so much the man as his mode of doing business that is objected to. The usual course of trade at home is for the merchant to import the goods in immense quantities at a time. He acts either as an importer on his own account, or as the agent of some foreign exporter. In either case he deals only in very large quantities. These large parcels get into the hands of the first set of middlemen, who as a rule work for a reasonable profit, and who re-sell to another class, who constitute the middleman, who is so much reprobated, and who disposes of his stock in larger or smaller quantities as may best suit the requirements of his constituents, who as a rule are the vendors who come more immediately into contact with the ultimate consumer. He it is, in conjunction with this vendor, who lays on the prices and leads the consumer to pay a much higher rate than he ought. In the matter of home produce, say beef, we find the retail consumer keeping almost all the profit in his own hands. The current price-lists tell us that the present price of the very best beef is 6 shillings per stone of 8lb., or 9*d.* per lb. Now we know that portions of this meat will sell again for rather less than this amount; on the other hand, the parts that sell at a better price are very much greater than those selling cheaply. We may, therefore, safely affirm that this sum of 9*d.* is a fair average wholesale price. Now let the consumer try what a pound of good meat will cost him in London, and he will understand how much profit the retail dealer makes. The same applies to the course pursued with regard to tea in India. From the published prices realised at the weekly auctions, we can easily understand why the shares of tea companies are, so many of them at least, at a discount, but we cannot understand from those lists why one cannot purchase a pound of tea in Calcutta under a price at least double that realised by the producing company. At random we take the present prices of retail houses in Calcutta:

		R.	A.	
Golden Tip Flowery Orange Pekoe	...	4	8	per lb.
Flowery Orange Pekoe ...	...	3	0	,,
Flowery Pekoe	...	2	3	,,
Orange Pekoe	...	1	13	,,
Pekoe	...	1	6	,,
Pekoe Souchong	...	1	5	,,
Souchong	...	1	3	,,
Broken Souchong	...	0	15	,,

And this at the very time when the average wholesale price of tea does not exceed 11 annas per lb. If the tea-planters of India wish their teas to secure a market here, they must make other arrangements having that object in view, and that such a market exists is shown by the fact that in the year 1878-79, the quantity of tea imported into India from China and elsewhere abroad was close on two million of pounds. The Indian tea-grower should be able to secure all this traffic for himself, and the importing of China tea should be quite an abnormal transaction.

M. M.

TEOSINTE "REANA LUXURIANS."

TO THE EDITOR.

SIR,—In an article headed "Reana Luxurians" in the *Indian Agriculturist* of the 1st October 1879, we are informed that "this grass is a native of Guatamala, where it is known by the name of "Teosinte." I lately sent a small parcel of seeds for distribution to friends in the Mysore district as "Teosinte." This being the name that it is known

by in its habitat, while "Reana Luxurians" is the name given to it by the President of the Agricultural Society of Paris. Further on it is stated :—"This Teosinte is *trepsacoem monastachyum*, this can only be another name for the same plant, and if so, does not in any way set aside the oneness of "Reana Luxurians" and "Teosinte." One gentleman wrote :—"Thanks for the Teosinte ; there is nothing of the kind in these parts. I have just sent to England for a supply. I have plenty of "Reana Luxurians." Now as I do not know where he got this information, all I can say is, that the article in your October's issue of 1879, has misled us as to the identity of the names, or that allowing it to be the best authority as to the identity, then surely sending to England for "Teosinte" seed was not at all necessary, while the seeds are to be had in India for the mere asking.

In the same article above referred to, it states, "mules, horses, oxen "throw themselves on the cuttings and devour all, even to the stalks "and roots, which shows it is a most saccharine vegetable." A medical gentleman, high up in the service, has come to the conclusion that horses are subject to great pains in the stomach after eating it. If this be correct, then no one will go to any expense or trouble to cultivate it for horses, when consequently its value will be entirely lost as far as fodder for horses is concerned.

Hoping some of your numerous readers and correspondents will kindly give such information as will be useful to all that take an interest in this subject.

OBSERVER.

22nd March 1880.

TEA AGENCIES.

TO THE EDITOR.

SIR,—I have been very much pleased to see you have taken notice of the deplorable position of the jute industry, and that your correspondent, ONE INTERESTED IN TEA, draws attention to one of the numerous heavy burdens we are suffering under in our tea industry.

I think it has not been sufficiently brought out that the agents of the Gowhatty Tea Company, Limited, in charging their Rs. 500 per mensem—equal to 12 per cent. on the gross proceeds of sales last season—have acted only in accordance with the Articles of Association, which were framed in the *rosy days*, when prospectuses were handed about amongst us promising large dividends, and it would then have been ungenerous to have framed these articles excluding agents from participating in the promised golden harvest they were good enough to offer to the public. It is not customary for individuals to draw less than their stipulated incomes, even when unselfish enough to feel that they are overpaid ; but from what I know of the public-spirited agents above referred to, I feel sure they have only to be asked to participate in the misfortunes of shareolders to willingly consent to the reduction of their agency commission to a fair and reasonable amount for the services rendered. They do not stand alone in their present exorbitant agency charge, and it rests with shareholders to bestir and help themselves in looking after their interests.

With the discovery that agents exist who, in addition to an annual or monthly allowance, charge commissions on stores, coolies, &c., and others who cannot account for Companies' funds, it appears high time that shareholders should take a more lively interest in the affairs of companies in which they have a stake than they generally do.

There is but little to be expected from the majority of boards of directors, constituted as they too often are of gentlemen not unfrequently under pecuniary obligations to the agents, or members of, or assistants to, the agents own firm.

Please give your kind assistance to

AN UNFORTUNATE SCRIPHOLDER.

INFORMATION WANTED.

TO THE EDITOR.

SIR,—Will you or any of your readers kindly let me know where I can get a thoroughly popular and practical treatise on the cultivation of sugarcane, and on the manufacture of sugar, molasses, rum, &c., also which sugarcane is most suitable for India.

R. O. B.

PROPER TIMES FOR SOWING.

TO THE EDITOR.

SIR,—Will you or any of your readers kindly inform me what is the best time for planting out and sowing the undermentioned :—

Ginger	Cotton
Turmeric	Castor-seed

I have started an experimental farm and any informations regarding the cultivation of the above, with the best soil suitable, will be thankfully received.

I mean to cultivate *Colgong* castor-seed, as it commands a better sale.

What would be the best kind of cotton suitable for cultivation in Bengal ?

RAOUL.

FOREST DEPARTMENT.

TO THE EDITOR.

SIR,—I regret to have to say that my last letter did not catch the eye of the proper authorities. It has been my conviction that unless Dr. Brandis changes his mind or makes room for another man, natives will never be allowed a fair share in this branch of the State service. I have already pointed out that natives are admirably fitted for executive service in the Forest Department, if a judicious selection is made. The Forest School at Dehra Doon is a move in the right direction. But though it was started about a year ago, it has not proved successful, for the simple reason that the arrangements are most defective. There are two classes attached to it—one for the probationers, and the other for the apprentices. The candidates for the former must possess a good knowledge of English, surveying and mathematics, &c., and for the latter, a smattering of their own vernacular is all that is required. The anomaly is that after passing the final examination, both obtain certificates of *Forest Ranger*, except in the case of Europeans or East Indians generally, and *exceptionally* promising native students *specially*, when certificates of Sub-Assistant Conservator will be granted. The preliminary obstacles thrown in the way of a native's getting admission into the school, and the relaxation of the rules in the case of the Europeans, betray the narrow mind of the framer of these rules. Now that the Forest School has been started, it is very desirable that it should meet with success. In order to this, as stated by me in my former letter, the Government ought to fix a certain standard. The Conservator of the School Forests may be selected as the examiner, and question papers should be sent to the different centres of examination which may be fixed at the head-quarters of each local Government. The candidates, without distinction of color or creed, should be allowed to appear in the examination, on payment of a certain fee, as in the case of the P. W. Department. The answer papers should be sent to the Director of the School Forests, who would admit the successful candidates in the Forest School. The certificate of Sub-Assistant Conservator should be granted to those who can finally pass the examination among the probationers, and of Forest Ranger to the successful apprentices. The rule that all candidates for appointment should have preliminary training for six months in a Forest division at their own cost, should be withdrawn. For this service will be mostly resorted to by middle-class men, who can little afford to pay for this expenditure. The well-to-do classes would not care for service at all, far less in the Forest Department.

In my last letter I referred to the case of Mr. Battie, who was a Forest Ranger, on Rs. 50, and was promoted to the rank of the Sub-Assistant Conservator on Rs. 200, thus overtopping hundreds of natives who ranked above him. In this I shall refer to Captain Wood's case. He has served as Conservator of Oudh on Rs. 900 for a long time, and his merits have always been recognised both by the local and Supreme Governments. For some reason or other, he is not a particular favorite of Dr. Brandis, and the result has been that on the occurrence of a vacancy in a higher grade of Conservators, the appointment was given away to Mr. Sykes Gamble, who was only an Assistant Conservator, but the *Personal* Assistant to Dr. Brandis for some time. Now, should not the Government of India interfere and put a stop to such a high-handed proceeding of the Inspector-General ?

Lord Lytton may be personally engaged in looking to the affairs in Afghanistan, but he has an able Secretary in the person of Mr. Bernard, and can he not look to the important details in connection with this department ? It is high time that the Government should redress all such grievances, and frame such rules as would render the working of the department as smooth as possible.

FORESTER.

BAMBOO FOR PAPER STOCK.

TO THE EDITOR.

SIR,—In my last communication I referred to the valuable monograph on the Bambusaceæ by General Munro, published by the Linnean Society ; since then I regret to record the death of that eminent botanist. To him and the late W. Sulpis Kurz we are indebted for the best standard works on Bamboo, the last publication by Kurz specially published in the "Indian Forester," gives

the most interesting details of the habits and universal uses to which this prolific land is applied throughout the Archipelago and Southern India.

Having enjoyed the privilege of corresponding with both the gentlemen referred to, from their publications as also from information gained from numerous other sources, I will briefly ennumerate some of the varieties of bamboo which appear most suitable for paper-making material.

Although suffering from the disadvantage of not having seen this gigantic grass growing in all its native tropical luxuriance, I have specimens of most of the varieties referred to, these being duplicates of exhibits supplied by the Indian Forest Department for the Paris Exhibition 1878 (sent me from Kew.) Besides these, which are mostly from mature stems, and not collected with reference to paper material, I have received others cut at the early stage of growth, and as mentioned in previous letters, I have carefully and practically tested and found them, as I anticipated, well adapted for that purpose.

The following abound throughout Burmah and Pegu : *Bambusa Brandisii* (wa-boe) *Bamb-Polymorpha* (kya-thorm-wa.) *Bamb. Gigantea* (wa-bo) *Cephalostachyum Pergracile* (Tin-wa or Teng) *Dendrocalamus Rembranaceous* (wa-yai) *Gigantooloa Macrostachya* (wa-net or Talagu) all these grow from 50 to 100 feet or more in height with long internodes and thin annulus or stems, due to which characteristics I find the fibre produced therefrom is finer, stronger, and the yield or propuce greater than from varieties with shorter internodes and thicker annulus.

Bamb. Tulda (Thaik-wa) *Bamb. Longispatha* (wa-ya) abound indigenously in Arakan : Dr. Brandis reports the bamboo forest covers by far the greater portion to the area of this province extending over thousands of square miles. Dr. Schlich reports, "I had to travel for days at the rate of half-a-mile an hour, having "four men (alternately two and two) in front cutting a passage just "wide enough for a man to pass through, the forest is composed "of *Bambusa Longispatha*, and *Bamb. Tulda*."

The supply therefore from the native jungle or forest both in Burmah and Arakan is practically inexhaustible, and the collection of the young season shoots due to the facilities afforded by the numerous rivers for floating, enables this valuable paper-making material to be laid down at a Central Stock Factory at very low cost. I am informed at from Rs. 7 to 15 per 1,000 stems—sufficient to produce from 1½ to 2 tons paper stock.

Bambusa Arundinacea, Bamb. Balcooa, Bamb. Tulda. Bamb. Stricta, prevail throughout Southern India, all of these will produce excellent paper material, although being somewhat less prolific and smaller in growth, their cost for paper stock, dependent however on local circumstances, may be higher than those above referred to.

At all times desirous to receive, as also to afford further information on this subject, sooner or later destined to assume an important position as a profitable industry in our great Indian Dependency.

THOS. ROUTLEDGE.

Claxheugh, Sunderland,
March 4th, 1880.

TEA BULKING.

TO THE EDITOR OF THE HOME AND COLONIAL MAIL.

SIR,—Some time since you were good enough to insert a letter from me, in which I alluded to the experiment which two or three tea planters had made of bulking their teas at the gardens before shipment. I then stated that it was somewhat early to pronounce a definite opinion on the subject, and I am still inclined to the same view; but a circumstance has occurred this week which bears upon the subject so closely, that I think it only right to put you in possession of the facts, that your readers may draw their own conclusions, and guide their policy of garden management accordingly.

On the 26th January the Borelli Tea Company offered for sale, at the London Commercial Sale Rooms, a shipment of 158 chests of tea, in eight lots, average say 20 chests in each, stated to have been bulked in India. Amongst these were two breaks Pekoe and three breaks broken Pekoe, so closely similar in quality, respectively, that it was difficult to make a preference. The remaining three breaks consisted of a Pekoe Souchong, a broken Souchong, and a broken Congou. When the sale commenced some dissatisfaction was expressed by several of the buyers at the apparently needless trouble which had been given them in having to taste five breaks instead of two (of the finer qualities), and the market being rather inanimate at the time, no satisfactory bids were made. The other three lots being complete in themselves and without duplicates, were sold. Shortly after the sale the brokers endeavoured to get offers for the five lots which had been withdrawn; but failing in this they accepted an all round bid for the string from one of the leading buying brokers. As soon as he obtained possession of the teas, he gave instructions to the Dock Company to bulk the two breaks of Pekoe together, and the three breaks of broken Pekoe together, and printed them for sale in their new condition as two breaks. The tea, of course, was not in any way improved. The market was in quite as depressed a state on the second appearance of the tea as it was on the first ; and notwithstanding the fact that it was now offered as secondhand, and not on account of the importers, the proceeding was viewed favourably by the trade, and both breaks were sold at a remunerative profit.

Tea planters can draw their own conclusions from this. It is clear that had the teas at first been in only two lots, a better result would have been shown to the garden. It is explained by some that the facilities for bulking teas at the gardens will not admit of treating more than twenty chests at a time. If so, common sense would suggest that if planters have not already the facilities they might easily provide them. There is no reason why it should not succeed if done carefully, and so as to leave no room for doubts as to its thoroughness in buyers minds. It has been said that "the man who makes two blades of grass grow where only one grew before, is a benefactor to the human race;" but, judging by appearances, the planter who makes one large break of tea into two or three small ones, is not by any means similarly regarded by the trade.

I am, &c.,

12th February. D. F. SHILLINGTON.

A CEYLON PLANTER ON TEA PROSPECTS IN AUSTRALIA.

TO THE EDITOR CEYLON OBSERVER.

MELBOURNE, 6th Feb. 1880.

SIR,—Having seen some remarks of yours in an Overland Summary on the subject of Ceylon tea, I send you a few lines to let you know what chance there is of a market being found for it here.

In proportion, to its population, this is the largest tea-consuming country in the world, and when visiting it some months ago, I was much struck with the vile decoction which every one seemed content to drink as tea. At present, the whole of the tea imported comes from China and sells in the auction rooms at prices varying from 8*d* to 15*d*., and it does not suit the merchants to have the Indian or other teas introduced.

I brought down some samples with me, and was told at once that it was not the slightest use attempting to introduce Indian teas, as the public would not have them.

I, however, sent a letter on the matter to the *Argus* and succeeded in drawing public attention to it, there will undoubtedly be a demand for your teas, once they are fairly introduced and made available to the public at a reasonable figure.

The Indian teas are undoubtedly too high priced for this market, but if the growers in Ceylon are not too grasping at first, and are willing to secure a sound and certain market for their produce in the future, I shall succeed in doing it for them in these colonies.

The samples which I brought down were tasted and reported upon by all the leading men here, and they all make the same report, *viz.*, "Good liquor but bad leaf." The leaf is too rough and irregular and buyers are, of course, guided a great deal by appearance. I sent up some offers to growers for their produce by last mail, and, if these are accepted, shall be able to give the public a fair trial of them.

Should the venture be successful, a steady demand for your teas will grow up ; if it is a failure, it is hardly necessary to say that this market will be closed to you for years. I have not yet heard whether you intend having a Court at the Exhibition here. It is getting rather late, to apply for space, and every other country in the world seems determined to do its best. It will tell very badly for Ceylon, should the Government and the community not make every endeavour to have it properly represented.

I shall address you again on this subject. Thanking you in anticipation for giving this a corner, I am, yours faithfully,

H. M. ROWBOTHAM.

SOLUBLE *versus* INSOLUBLE PHOSPHATE.

TO THE EDITOR N. B. AGRICULTURIST.

SIR,—Your notice of Mr. Yool's results obtained with ground coprolite phosphate and superphosphate as manures for turnips, cannot be properly called a test of value between soluble and insoluble phosphates.

The manure superphosphate is composed of two salts, sulphate and phosphate, while ground coprolites consist only of one, a phosphate of lime, consequently the turnips grown upon the superphosphate had two of their chief inorganic constituents, sulphuric and phosphoric acids, while those upon the ground coprolites had only one of these acids phosphoric; and to this additional constituent, sulphuric acid, in the superphosphate plot of turnips, may be attributed the better result, and *not* to the solubility of the phosphates.

Six cwt of ground coprolite phosphate, against six cwt. of superphosphate, '*both good of their kind*,' is stated to have been used '*upon the same area of land*.' As such, the turnips upon the former would have an advantage in point of phosphates over those upon the latter manure, as six cwt. of ground coprolite phosphate would contain one hundred per cent. more phosphoric acid than that of the soluble phosphate in the superphosphate applied; and from phosphate in a fine state of division, as that of ground coprolites, the action of the soil would render available sufficient phosphoric acid for doing all that phosphates could, or are required to do, in producing a crop of turnips.

As an inorganic constituent of manure *necessary for application* to turnips, sulphuric acid as actual nutriment stands first, and phosphoric acid second; which is clearly shown in statistics of the chemistry by all analysts of eminence—British, French, and German. The weight of sulphuric acid necessary for application for turnips has been estimated by the same authorities as being about one-third more than that of phosphoric acid, or in other words, phosphates; and what is still more conclusive as to its importance as a manure for turnips, and for the whole of this class of plants when cultivated as green crops, is the deficiency of sulphates in comparison with phosphates in the soils upon which such crops are grown.

Phosphates are found upon the average in loamy, clayey, marly, sandy, and chalky soils, to be seven times more abundant than sulphates; consequently the only logical conclusion to be drawn is, that as turnips and the same class of green crops require about one-third more sulphuric acid as their actual nutriment than phosphoric, and from the soils upon which they are grown containing upon the average seven times more phosphates than sulphates, sulphuric acid for such crops must have a higher agricultural value. Taking the subject from another point of view, results in the field since 1854 point to the great value of sulphuric acid.

The exhaustion of the principal guano deposits about that period, except Peruvian, gave an impetus to the trade in manufactured manures, and which owes its great progress to sulphuric acid. Experimental agriculture twenty years previously had been conducted to a greater extent than it is at present, and by a class of men of higher agricultural research. Ground phosphates had been fairly tried, and many other inorganic constituents considered necessary as manures for promoting the growth of green crops, yet no progress was made until sulphuric acid had become a part of their composition; and no sooner was this done, and means were found to produce sulphuric acid at a reasonable price, than its consumption with phosphates as manure sprang almost at once into an enormous trade, which is still increasing; and the turnip crop from its introduction has become tenfold. The cost at which sulphuric acid can now be produced is not one half of what it was ten years ago, and at this it cannot fail to be one of the mainstays in maintaining the fertility of land under agriculture; for, apart from its value as manure for green crops, its solvent properties exceed those of all other acids; and when in a *proper form for direct application to soils*, its action upon all their inert mineral matter, such as potash and phosphates, locked up in the heaviest and best soils, would undoubtedly render them more fertile.

As an adjunct necessary to apply with guano, sulphuric acid is of the utmost importance; as such manures as ammoniacal or phosphatic guanos, which have passed through all stages of decomposition, and the sulphurous compounds originally in the organic matter of birds' or animal dung composing them having been dissipated, it is to the absence of these that the produce of crops manured with guano have been found inferior in quality to those produced from farmyard dung, where both sulphuric and carbonic acids are present, and to which the better quality of crops well known to every practical farmer may be attributed. Consequently Mr. Yool need have no fear about inferior quality of turnips, or of their containing more water when grown upon superphosphate, without the growth is *too* much *forced* and the *bulbs too large*, as sulphuric acid is one of the principal *constructors* of organic growth in plants; and their albuminous compounds, which represent the highest class of nutriment, cannot be formed without sulphuric acid is present in soils, or is a constituent in manures applied in their cultivation.—I am, &c.

B.

CULTIVATION OF THE PEA.

TO THE EDITOR.

SIR,—With the endeavour to further a rotation of crops in the drier portions of the colony where seeds (grasses) fail, I send the following:—In my harvest report last season, from this district (Oxley) I said "I have a good deal to say about the pea," and promised to send you a few ideas upon the subject. I will now endeavour to do so, otherwise time will run into another "harvest return," which would appear very remiss on my part.

I then said "I thought they (the pea) were destined to be the farmer's best friend as a change, and possibly be the means of establishing a rotation." I was glad to see that several of your correspondents in their harvest reports, were giving their attention to pea cultivation. One said: "They clean the land, and wheat-sick land will carry a good crop of peas, and the following crop of wheat will be quite as good, if not better, than if the land had been in fallow." Another, "Peas are in great favour, and in my opinion, deservedly so, being great cleaners of the soil, cheap to harvest, and as renumerative as any corn crop," &c. One individual, however, gave a very lame and unfarmer-like excuse thus:—"Peas—A few grown with fair results, but the great draw-back to pea cultivation is that they come in at harvest time, and consequently get neglected and shed on the ground."

Regarding leguminous plants in general, such as peas and beans, as a rotation crop, these remarks cannot apply so much to those portoins of the colony enjoying a comparatively cool climate, either from latitude or elevation. In those districts there cannot, or should not, be any difficulty whatever—as a criterion, we may say, all those districts where the potato and other roots grow to perfection, and where ground can be laid down to grasses, clovers in particular. In these districts it is the farmer's own fault if he has no regular system of rotation. There is no difficulty of farming profitably too. Fortunate men thus situated, say I, In fact, the saying is, "any old woman could farm there," peas or no peas. But when we come to the hot and dry portions of the colony, where roots and grasses fail, there you must set your wits to work, and lucky will you be if on one hundred acres in corn, you can show a balance on the right side, after the ground has been cropped for a few years. It is on such land we must cast about for a change, and strive to form a system of rotation, unless science can show us a renumerative "artificial manure" for general purposes, point out what soils it is suitable to, and show us where it is to be procured, and the price we ought to pay for it; something definite, and tangible, so that upon dry soils we may ensure a crop; for although we have had a plethora of talk upon the science of farming for some years now, it has had but little pratical result as far as I know. We must therefore fall back on the system of rotation, for manure we cannot make for one-twentieth part of the land under crop, and even that manure in most cases is procured upon the "rob Peter to pay Paul" system; the cattle rob the pasture in the day time, and deposit the same at night in the yards. But how about the poor grass land?—that, at east, must shift for itself. Bone, flesh, butter, cheese, wool, &c., being continually drawn from mother earth's bank, and nothing whatever placed to credit. This will never do. But to return. The pea therefore appears to be an exception to almost all other farm plants (clovers and rape have some peculiarities, however, but of these another time), science has never been able to explain satisfactorily in what way they provide themselves with nitrogen, not even the famous experimentalists, Messrs. Lawes and Gilbert. They only "suppose that the pea has the power of drawing it from the atmosphere," for, strange as it may appear, on land exhausted apparently of almost every element, they are richest in, *viz.*, the phosphates (the principal corn element), they have the power of procuring the same in some way or other and not only so, but leave the very same land in a better state to grow another crop of wheat, rich in the very same elements—in fact, not only a change, but a preparation for another, crop of wheat. Thus—phosphoric acid in 25 bushels wheat—grain, 11·47; straw. 8·15; total 19·62. Do. in 30 bushels of peas—grain, 16·9; straw 8·11; total 24·20 Thus we see that 30 bushels of peas take more phosphoric acid out of the soil, than 25 bushels of wheat—24·20 against 19·62. This is one of the mysteries whereby Nature manipulates her wonders, and observed long before agricultural chemistry was thought of, as the old rhyme says:—

> "The essence which within them lurkes
> Doth help another race to be;
> Soe God in endless circle workes,
> And thus ordains His alchime."—OLD M.S.

This, then, is peculiarly the farmer's province, to watch the results and practice, and thereby, in great measure, make himself independent of science. This is why I think farmers in the drier portion of the colony should endeavour to establish the pea in farming rotation of crops. A good rotation, I think would be—first, wheat; second, peas; third, wheat fourth and fifth, grass; or rest with all the manure put on the same and fed with sheep. Anything is better than a bare furrow, as nearly all our outlying soils are deficient of humus; "Nature also abhors a vacuum." But mind, and give so valuable a plant a fair chance. Cultivate (dwell upon that word there is great meaning in it), them, not just throw them on the land, and leave all to Providence; the best faith, which gets the blessing is that which uses the means. Should the ground be stiff, plough twice, the, scarify, and drill if possible, and as the pea is eminently rich in lime and potash—(thus—lime, pulse 2·58 straw 90.25, total, 92·83; potash, pulse 17·50, straw 8·50, total 25)—these should be provided. In clay soils

However, the potash might nearly be dispensed with. The advantages of drilling should be obvious to all. It will come to that ultimately, even our corn crops; as many now perish from being hide-bound with winter rains, the soil should be aërated, but fallow crops more particularly should be drilled. A very efficient drill can be purchased in England for £12 to drill peas, &c., 8 rows from 15 to 24 inches apart, with manure, same time to the amount of 12 bushels to the acre with regulator to deposit more manure in poorer portions of the field, consequently the quality of the soil and crop are rendered more uniform. It is always with reluctance instead of pleasure that one mentions machines when we have such enormous duties staring us in the face. This and a pea-puller £4 in Melbourne (I am now using one), and although not a perfect implement, it is cheap and labour-saving, together with a small horse-hoe are all the extra implements required. The hoe should be used as long as the horse can walk between the rows.

The question will now arise, "If every one went into pea-growing, would not the price be nominal?" I do not think they will ever be lower than maise, and they are far preferable for feed, say 3s. per bushel. But remember you have this instead of bare fallow. Say 30 bushels at 3s., £4 10s., nearly as good as 26 bushels of wheat at 5s., and remember again your land (strangely) is in a state to bear another crop of wheat. But in case they should become a drug in the market, and thrown upon our hands, I will on a future occasion say a little about "what to do with the pea, as feed for farm use."

We have just stacked our pea crop, and I am very well pleased with the as yet apparent yield, not having thrashed yet. The portion of the field which had peas on last season, at the rate of 40 bushels per acre, was put into wheat this season side by side with farm-yard manure; the pea ground, without any manure, is much the best crop, in fact some of it has gone down.

E. H.

King River, Oxley.

AGRICULTURAL EXPERIMENTS.

TO THE EDITOR OF THE "CEYLON OBSERVER."

SIR,—In the "Journal of the Chemical Society" for February, among the exracts from foreign journals, there are a few that should interest an agricultural community.

"Experiments on the Manuring of Barley, by P. Wagner and W. John (Bied. Centr. 1879). The soil in which these experiments were carried out, was a sand containing 1½ per cent. of humus, the phosphate being applied in the following experiments one day before, and the nitrogen (in the form of Chili saltpetre) the day after sowing. The following table shows the quantities of manure applied per hectare and the yield obtained." I may mention that a hectare is equal to 2·47 acres and a kilogramme to 2·2lb.

		Corn. kilos.	Straw. kilos.
(1)	Unmanured	4120	3770
(2)	20 kilos nitrogen	5280	4890
(3)	50 ,, soluble phosphoric acid	4570	4490
(4)	50 ,, soluble phosphoric acid with 20 kilos nitrogen ...	5320	4920
(5)	50 kilos phosphoric acid in the form of freshly precipated phosphate of lime and 20 kilos nitrogen	5600	5110
(6)	50 kilos soluble with 43 kilos insolub'e phosphoric acid in form of phosphorite with 20 kilos nitrogen	5970	5370
(7)	35 kilos soluble and 30 kilos insoluble phosphoric acid as above, with 20 kilos nitrogen ...	5660	5350
(8)	50 kilos soluble phosphoric acid in form of phosphate of potash with 20 kilos nitrogen ...	6170	6500

Turning to Johnstone and Cameron, we find that barley, the subject of the foregoing experiments, contains the following ash constituents per 100 parts :—

	Barley grain with husk.	Barley straw.
Potash	21·28	19·32
Lime	2·40	7·00
Phosphoric acid ...	33·17	4·83

Barley seed contains 1½ per cent. of nitrogen.

The abstractor goes on :—"It is evident from the above experiments that although the soluble phosphoric acid yielded poor results, the use of saltpetre proved very advantageous. The reason of this may be looked for in the fact that the soil was so very poor in lime, as not to be able to arrest the phosphoric acid during its percolation through the soil after rains, thus only a small quantity of it came into actual contact with the roots of the barley." In Ceylon soils, oxide of iron would arrest the phosphoric acid. "This of course was different in the cases of experiments (5), (6), and (7) where part at least of the phosphoric acid was applied in the insoluble form, and larger yields were the result.

With regard to experiment (8) the authors do not explain whether the remarkable yield obtained was the result of the way in which the phosphoric acid was combined or of the presence of potash," the latter I should think.

"Manuring Experiments with Oats. By C. Jenssen (Bied. Centr. 1879). A field was marked off into eleven plots of 975 square metres each; of these, two were not manured, the remaining nine being treated with quantities of manures of various sorts equal in value commercially. The table following shows the various manures used and the resulting produce :—

	Quantity applied per Hectare. Kilos.	Grains. Kilos.	Straw. Kilos.	Chaff. Kilos.
Chili Saltpetre	19	201	268	29
Unmanured	—	151	190	18
Bone-meal	25	181	227	21
Bone-meal Superphosphate	25	173	216	21
Ammoniacal Superphosphate	22	177	199	20
Peru Guano	16	181	209	17
Unmanured	—	168	191	16
Bone Guano Superphosphate	31	191	242	17
Animal Manure ...	17·5	172	213	18
Stable Dung	1100·	194	233	23
Majellon Guano Superphosphate	29·5	170	200	11

The above table shows that Chili saltpetre, and, next to it, stable dung and bone guano superphosphate, produced the best yields. Further researches are necessary to establish any conclusions from the above."

"Absorptive Power of Soil Constituents for Gases. By G. Ammon (Bied. Centr. 1879). The substances used in these experiments were sand, kaolin, carbonate of lime, hydrated oxide of iron, gypsum, clay, and humus, all powdered to various degrees of fineness. The author tried the effect of aqueous vapor and ammonia on these substances at various temperatures; his experiments shewing that the most favourable temperature for absorption lay between 0° and 10° c., and that the quantity absorbed varied directly with the fineness to which the substance had been powdered.

The following are the numbers obtained 100 cubic centimetres of each substance being used, and the water being calculated by volume in state of gas"

I only give the results of the experiments at the two highest temperatures, as these come nearest to the Ceylon temperatures.

Cubic centimetres of water vapour condensed by 100 c. c. of

At		Humus.	Hydrated oxide of iron.	Quartz.
20°c	(68°F)	26,789	98,999	277
30°c	(86°F)	16,497	54,753	99

Carbonate of Lime.	Kaolin.
962	1,541
233	1,335."

From these figures it is easy to see how valuable oxide of iron and humus must be in our Ceylon soils to enable them to resist drought.

"Of ammonia gas 0° c. the following quantities were absorbed :—

By humus.	By hydrated oxide of iron.	By quartz.
29,517	38,992	938

By Carbonate of lime.	By Kaolin
1,552	2,417"

The greater absorptive powers of oxide of iron and humus are again very marked; but the experiments having been made at the freezing temperature, the absorptive powers of all are of course greatly higher than at temperatures prevailing in Ceylon.

"To show the influence of oxide of iron on the absorption of nitrogen by the soil, the author made the following determinations, in which ferruginous sand and clay, and the same substances freed from iron are compared in their absorptive power for nitrogen,

100 c. c. of sand containing iron		absorbed	217	c. c.	nitrogen.
do.	pure	,,	101	,,	,,
100 c. c. of kaolin containing iron,		,,	1687	,,	,,
do.	pure	,,	846	,,	,,

In the absorption of oxygen, gypsum stands higher than oxide of iron, and next to it for the condensation of nitrogen.

I trust the foregoing may be of interest to some of your readers,

M. C.

Colombo, 8th March 1880.

The Indian Agriculturist.

CALCUTTA, APRIL 1st, 1880.

TEA BLIGHTS.

On a recent occasion we devoted a few words to the consideration of the so-called leaf disease of the coffee plant, on this we propose making a few remarks on the blights that afflict the tea plant. We do not intend enlarging on them and treating each separately, as we hold the same opinion of them as of the coffee leaf disease, and consider them all as so many exemplifications of the same disease, that being not a leaf, but a root disease.

Let us go to the root of the matter, and instead of wasting time, imagining what will cure the leaf—let us endeavour to put the root right, when we may safely leave Nature to cure any irregularity in the leaf. We need not recapitulate then reasons we gave for holding this opinion, as those already given in the elaboration of our ideas on coffee leaf disease (Vol. IV. page 399), apply with even greater force with regard to tea. In regard to coffee, the method of treatment rendered necessary by the exigencies of commerce, does not amount to a positive thwarting of Nature, so much as to an effort to compel Nature to do more than she would, in the ordinary course of events. Nature, in her efforts to reproduce, does not as a rule exert herself to such an extent as to kill or even injure the plant, and while she is calling on the plant to make a vigorous effort towards this consummation, she takes care that this effort shall be made while the plant is at its best. Hence we find in all plant-life, that the plant is in the highest state of perfection at the ripening of the seed, and immediately thereafter, the season analagous to hybernation in certain animals sets in. The seed having ripened, the plant at once commences to rest—and the tea plant if undisturbed now, would show no signs of life from the end of October till the middle of February, a period of three-and-a-half months. In colder climates the recess would be longer, as in the Upper Provinces where it lasts from the end of October till the middle of March, when the first symptoms of fresh life show themselves, and what is our treatment of the bush during this time. Why we ruthlessly cut it down to within 18 or 20 inches of the ground, we remove all the young leaves which the pluckers may have left, and leave the plant bleeding at a thousand pores, at a time when its energy is in abeyance. We are not objecting to winter pruning *per se*, but merely showing how it must tell on the vitality and vigour of the plant. Now the roots have to make a vigorous effort to repair this damage, and this at a time when plant-food, owing to the dryness of the season, is not available. However, the tea plant is peculiarly vigorous, and manages to recover itself in time to take advantage of the advent of spring, when it leaps into new life with an energy which is astonishing. The result of the heavy winter pruning, and of the plant's vigorous effort is at once apparent in an astonishing growth of young wood and tender shoots, clothed with the most delicate leaves and buds. This the planter calls the first spring flush, but which the plant, if it could speak, would call fresh lung-power to replace that ruthlessly removed during its hybernation. And how does the planter treat these new lungs, why by at once plucking them off. He has to make up his estimate, if he can, and he cannot afford to indulge in sentimental rubbish of this sort, even if he ever gave the matter a thought. We are not finding fault with the planter, he would not be faithful to his trust, if he neglected to pluck such flushes. We are only looking at how such treatment affects the plant itself, and in how far it militates against the chances of the plant maintaining a general good bill of health. Let us take another excursion into the planter's routine of work. We have said before, that Nature's great aim in all plant-life is reproduction. In the tea plant, then, we will naturally expect all her efforts tending to the strengthening and sustaining of the plant with the ultimate view of producing a crop of seed. Here the planter steps in, and says he does not want seed but leaf. All his pruning and general cultivation are aimed at this, and it is here that he most particularly makes an effort to thwart Nature. Nature's object being to produce seed, the planter's to prevent the growth of seed, at the same time he wishes to keep the plant abnormally healthy, as he wants more leaf than Nature would ordinarily give him. The tea plant is naturally of so vigorous a habit, that the planter can do all this with impunity for a time, but he must not forget that a time comes when the plant's vitality begins to show signs of waning. Before, however, treating of that we have one more peculiarity to speak of. Planters do not require to be told that the China variety is a bush in its habits, while the indigenous is a tree, the hybrid partaking of both, but more particularly of the latter. The natural result of growth, in ordinary cases, is the attainment of maturity. In the China tree we find by experience that being a bush, it will seldom grow over six or seven feet high, while the others will grow forty feet high, if let alone. This is exactly what the planter will not do, he will not let the growth alone, and every winter he carefully cuts the plant down to *his* ideal of what it ought to be, he of course looking at it from a leaf-producing point of view only. We can well understand that this must be detrimental to the plant's health. In the case of the China variety the damage done in this way may not be so great as *it* being only a bush in habit at the best, is not so much damaged by being kept down, but with the indigenous or the many varieties of hybrid, the case is vastly different. Here we have a plant naturally growing into a tree, compelled to remain a bush year after year. Hence we find that blights are usually confined to those districts where the indigenous *ját* and its hybrid varieties prevail. In fact we have not heard of blight attacking China plants so extensively. While the plant above ground is so treated, that under ground is of course not interfered with, and we have the anomaly of a tree under ground, and a bush above. We do not say that this should necessarily be fatal to the life, or even to the health of the plant, but we think we are warranted in assuming that this, and the other operations performed in cultivating the tea plant commercially, cannot fail to have a detrimental effect on it ultimately, because these operations are in very many instances carried on in direct opposition to the ordinary operations of Nature.

One more possible source of these blights. Mr. Cripps recently analysed the ash of the plant and found it as follows:—

Potash	39·22
Soda	·65
Magnesia	6·47
Lime	4·24
Oxide of iron	4·38
Protoxide of manganese	1·03
Phosphoric acid	14·55
Chlorine	·81
Sulphuric acid	trace
Silicate	4 55
Carbonic acid	24 30
	100·00

and on this he remarks:—

"The tea plant is one which extracts from the soil very large quantities of potash and phosphoric acid; and it is to replacing of the

these constituents that the attention of the grower should be directed. It would appear that phosphoric acid and potash are most necessary for the full development of the tea plant, and, unless stores are developed from the subsoil, or their constituents are applied, in the shape of manure, the soil will become exhausted, and disease of the plant a natural consequence of such exhaustion."

Have we done our duty in this connection. While stating, as we have previously done, that sulphur and lime cures, or in fact any other cures which aim at curing a leaf disease, must from these considerations fail, we do not for a moment undervalue efforts made in the proper direction for curing those diseases. Our contention is, that they are not leaf diseases at all, but root or radical diseases, due largely to our mode of cultivation, a mode necessitated by demands of the industry, and therefore unavoidable. Were they the results of ignorance in planting education, they could be remedied by the introduction of a little common sense, but being unavoidable from the very nature of the industry, we must look forward to a continuance of the causes leading to this unhealthy state of the plant, with a view to finding out a remedy to be applied in such a way, that the plant may be helped to overcome and neutralize those continual demands made on it, and how shall we set about this? If we meet with an accident, whereby, we will say, our arm suffers a wound, we at once set about curing the wound by outward application, such wound being purely a local and accidental affair, but if an eruption shews itself on any part of the body, the skilful physician is not content with the use of ointments and lotions, he knows that this is no local disease, but that there is something wrong internally, most probably in the blood, and his efforts are therefore directed towards putting that right, which effected, the local exemplification of the disease speedily disappears. When an athlete is in training for some exceptionally hard work, his trainers nourish him with such food as will best enable him to withstand the demands about to be made on his muscle-power, it may be. Such is the position of the tea-plant. Left to itself Nature will see to it, but if we, for our own purposes make demands on it which Nature never intended or provided for in its organization, we must in common justice so nourish it, that it may be materially helped to withstand those demands, without detriment to health. We have neglected this and an unhealthy habit is the result. A good deal of discussion took place sometime ago as to whether white ants ever attacked a living plant, some holding that they did, and based their opinion on personal observation. They had repeatedly seen living plants attacked by white ants. The other side affirmed that it was utterly impossible, because it was in direct opposition to the nature of the white ant to indulge in anything that partook of life. The truth was ultimately found to lie between the two opinions, and to be, that the white ant would never attack a healthy plant. Now this we consider to be the case with the tea plant. From incessant efforts to overcome the damage sustained by our mode of culture, the plant has ceased to be really healthy, it has become debilitated, and therefore open to the attacks of sundry parasites which would not otherwise touch it. If this line of reasoning be correct, one of two things is open to us. We must either give up tea as an industry, or we must adopt a more generous mode of treating the plant. It is clear that if we are to continue the industry, we must continue to inflict this damage on the plant, and therefore, we must concentrate our attention on the subject of supplying the plant with extra nourishment,—and this we can do in two ways, we must supply the proper constituents necessary to rehabilitate the plant, and we must improve our cultivation. We are not now concerned to recommend any particular manure. Each planter must be the judge of his own requirements in this respect, but that *some* more generous treatment is necessary, we think there can be no doubt. It is no answer that the industry will not stand it. It has stood it in China for centuries, and if we cannot afford to cultivate on sensible principles, we had better give it up altogether. We quite admit that as at present constituted, the industry would cease to exist, if burdened with the cost of this manuring, but we must not forget how often a manager excuses the deficiency in his estimate by a reference to the attacks of blight, and that this deficiency is often as much as two maunds per acre. If the generous treatment which we suggest removes the blight, the tea industry will be thoroughly able to bear the cost of the experiment, and if a pressure be experienced, a saving must be effected elsewhere in the cost, as *this* outlay we consider of vital importance, and absolutely necessary if the tea industry is to survive at all.

EDITORIAL NOTES.

THE recent memorandum on wheat in the North-Western Provinces and Oudh, by Mr. Wright, Magistrate of Cawnpore, does not in reality tell us much that we did not already know, but it places certain facts before us in a form fitted to impress on us the importance of the subject. There is one aspect of the case which does not, however, seem to have attracted the notice it deserves, and it is the relative value to the ryot of an increased outturn. In generalizing on the fluctuations in price of the articles at the point of production, he lays it down as an axiom that "an average rate of 40 lb. per rupee would pay the cultivator, the collecting agents, and the exporter, well." We are concerned here with the first only. Forty pounds, then, per rupee, pays the cultivator. That is to say, in round numbers, two rupees per maund of 3,200 tolahs. We are thus exact, as the maund varies so much in different localities. This supposition is based on the outturn of the district under notice. That outturn he makes out to be 700lb. on the average. Now, if this "pays the cultivator," we take this to mean that after he sells his crop at two rupees per maund, he has say, five rupees per acre left as clear profit, for we cannot suppose it could with justice be said that a crop "paid" the grower, unless it gave him a little profit over and above his actual outlay, and we hardly think Rs. 5 too much for this allowance. If, then, a crop of 700lb. per acre pays the cultivator, how would one of 1,600lb. do so? This latter is about the English average, and if, by improved modes of cultivation, we could increase the ryot's outturn, his profits would be increased in a much higher ratio. For instance, for every maund—valued at two rupees—which he produced over 700lb. per acre, we might safely say that the ryot's share would be at least one-and-a-half rupees, consequently an outturn of 15 maunds would leave him each year Rs. 10 per acre richer than if he only turned out 8½ maunds—his present average. The increased production might tend to lower prices, but on the whole he would benefit largely, by being enabled to improve his cultivation; and we are glad to find the Government are gradually becoming more alive to the great importance of this subject.

THE Government of Madras has we observe with satisfaction, agreed to Mr. Benson's proposal that the free distribution of seeds and models of implements of husbandry to "all who are anxious to experiment with them," should be continued as heretofore. This is very praiseworthy on the part of the Government.

A RECENT supplement to the *Calcutta Gazette* contains an important resolution bearing on the subject of the collection of manures, and the modes adopted by the cultivator with that object in view. The plan most thought of, is a system styled the cattle-box plan, and the co-operation of Government officials and of private individuals is sought to be enlisted in the attempt to obtain reliable information on the subject. We are pleased to notice that the Government of Bengal has been led to consider this subject from the perusal of a report of the Bangalore

Experimental Farm, and of an article in this journal, entitled *manures and their classification* which appeared in the September number of 1879, and which has been reprinted in the *Calcutta Gazette* for 3rd March.

WE observe with satisfaction that it is at last seriously proposed to utilize the Wards Estates for the introduction of agricultural improvements. It is astonishing that this was not done years ago. True, something *has* been done, but in such a manner that little good has resulted. Great results might be anticipated from this movement were the chances not so great that the Government will go the wrong way to work. We note that a beginning has been made by appointing a civilian officer in charge of a large estate of this sort to institute and superintend improvements in agriculture, with the ultimate view of showing what can be done by adopting improved methods. We are not informed where this district is or who the officer is; and it may be uncharitable to suspect that he has been appointed to this post, not because of any special qualifications he possesses, but because he is a "civilan officer." Yet this is the reason why so many Government schemes fail. The men are not selected for the posts, but the posts created for the men. And the result is disappointment to all concerned. It appears to us that it is our duty to do our utmost for the improvement of those estates, apart altogether from our very laudable desire to make them model farms. When a man undertakes a trust, he is bound to exercise the best knowledge and skill at his command in regard to it. Hitherto we have done little for these estates beyond economising their incomes. We have done nothing in the way of improving the condition of the people. Each estate ought to be really a model estate, from every point of view, and while we introduce an improved system—or what we consider an improved system—of land-laws, we should not neglect the improvement of the modes of tillage. When we read the administration reports, which are being issued so freely, we find five or six hundred pages devoted to the exemplification of our doings in a fiscal direction, and perhaps four pages on agriculture! This is not what ought to be in a country where agriculture is the stay of the people.

FROM the Administration Report of Assam for the year 1878-79, we learn very little that really interests the public. These reports may contain matter worthy of perusal by a few district officers, but we question the expediency of spending so much money on them, not to speak of the labour expended on them by officers who might be much better employed at other work. Is it not possible to tell us in these reports what is being done to open up the resources of the province? Here we have a report covering 300 pages, and all we are told of agriculture is contained in 8 pages, and is of the barest nature possible. The tea industry of Assam, which is of such vast importance, is disposed of in two-thirds of a page of information, which practically tells us nothing. We were anxious to learn what had been done in regard to minerals, about which so much has lately appeared in the daily press, but we look in vain; a couple of bald pages are all we find on a subject of absorbing interest: manufactures, too, take up two pages. Can nothing be done to make these reports more interesting? Under the heading of revenue, we are told something about the general progress of several branches of trade, but only in so far as the revenue is concerned: nothing whatever from a commercial point of view. From this one is almost forced to the conclusion that the Government do not concern themselves with material progress, so long as they manage to collect the revenue. We are not specially finding fault with this particular report, which is evidently compiled very carefully,—our objection lies against the system. All these reports are on the same model, and rightly too; but then, the model provided for the guidance of reporting officers should be a good one, otherwise all who follow its leading will continue to compile uninteresting and useless reports.

THE salient features of the Agri-Horticultural Society's show at Madras, were the local grown vegetables from Australian seed, the use of which deserves special attention; experience having already proved it superior to that imported from England for Indian cultivation. It is better adapted to the climate than European seed, it germinates more rapidly, and produces hardier plants.

MR. HARMAN, M.R.A.C.—This gentleman who it will be remembered, was Superintendent of the Mysore Government Experimental Farm at Bangalore, left for Madras *en route* to England for a few months' holiday. After this Mr Harman will we understand return to India having accepted employment under Messrs. Parry & Co., Madras, who we believe, will utilise Mr. Harman's valuable sevices in connection with their numerous coffee-estates in the Wynaad.—*Bangalore Spectator.*

EXPERIMENTS have for some years now been made by the Agricultural Department in selected parts of these provinces, with Australian and English wheat. These experiments have not been confined to ryot or zemindary estates, but have ever been tried in the Government forms and in villages of Court-of-Ward's Estates under the special supervision of special officers. The results of the several attempts to grow foreign wheat in these parts have tended to prove the superiority of the best wheats of these provinces—a fact which has led the local Government, on the recommendation of Mr. Buck, to decide "that the best course by which to secure improvement of wheat production in the N.-W. P. and Oudh, is to extend the distribution of the best provincial wheats, grown in a limited area, to other parts of the provinces rather than to import foreign seed.—*Indian Herald.*

THE *Pioneer* tells us that "a large portion of the district of Cawnpore has become infested with a plague of rats (*musa-gardi*, as the natives call it). The rats cut down the unripe corn, strip off the half-formed grains, and, curiously enough, in many instances, lay them symmetrically on the ground. So far the ravages can only be prompted by a pure instinct of mischief, for no crop is ripe enough for food. But the prospects of the future harvest are seriously affected by this pest, traces of which are plain enough in nearly every field, either in compact blocks or in paths intersecting the field in every direction. The damage so far has been estimated at about two annas in the rupee; but the rats have nearly a month before the harvest, in which to double their average. The cultivators seem helpless: the village pariah is not a good ratter; cats are not procurable; but the mongoose is in great demand. A simple form of rat-trap is used here and there; but, as a rule, the ryot folds his hands and looks upon this last burden as incurable and irremediable."

INDIGO TRADE.—The indigo trade in Madras is likely to assure large proportions since the Government have resolved to exempt that dye from export duty. To give one an idea of the trade it may be noted that, in the steamer *Poona* which left the roads on the 7th ultimo, 728 chests of indigo were shipped from Madras, the largest lot was sent to Suez. In the month of January 7,252 cwt of indigo were shipped from Madras of the value of Rs. 16,91,116. Of the total quantity exported 5,004 cwt. were sent to Great Britain, and 1,604 cwt. to Suez.—*Madras Standard.*

A CORRESPONDENT writing from Mauritius to the *Straits Times*, says:—"A new method of extracting the saccharine matter from the cane, so advantageous that its practical adoption seems almost an Utopia, has lately been projected here by one of our planters who has already secured his invention by a patent. No crushing rollers are used, but the canes are reduced to a pulp by a system of vertical and horizontal saws, and the whole of the saccharine matter is afterwards extracted from the mass. It is well known that great waste of sugar existed from the use of the cane crushing mills generally used, but no remedy could be found. The inventor of the new process promises an increase of 40 to 50 per cent. in future returns from the cane."

Two of the most important works undertaken by the Agricultural Department of N.-W. Provinces, have been the development of a plough calculated to meet the requirements of native cultivators, and the development of a cheap water lift for the same class of people. The Indian plough is an excellent supplement of its kind, but is, what is known to English farmers, as a grubber or sub-soil cultivator, and is not in English farm language a plough at all. Native cultivators have hitherto refused to accept English ploughs, or ploughs made in this country on English principles, on account of their excessive weight, draught, and cost, which are ordinarily about 60lb., 2 cwt, and Rs. 25 respectively. After several experiments, at the Cawnpore farm, the Agricultural

Department have succeeded in turning out a plough to which the native cultivators have taken very readily. The new plough weighs 30lb., has a draught of 1 cwt., and what is most satisfactory, it costs only Rs. 5. Three hundred and fifty of these ploughs have already been sold to ryots and zemindars, who have expressed considerable satisfaction at the manner in which they work, and the demand for the ploughs has so largely increased lately, that Government have ordered their manufacture on a very large scale. The "new cheap" water-lift, which has been introduced, can, we are told, be constructed in any native village for Rs. 15, and has been found so far more effective, at depths of 20 feet, that several ryots have abandoned their own lifts in favor of those of the Government pattern.

THE area under cultivation during 1878-79, in the Central Provinces, was 14,808,667 acres, while in the previous year the cultivation had reached 15⅞ millions of acres, that is to say, the district returns gave 15⅞ millions as the area sown during that year; there was, however, an error in the returns of the Shambalpur district, which the completion of the land revenue settlement in that district made it possible to correct. The aggregate discrepancy in the cultivated area between the two years compared, to the extent of 411,981 acres, is thus only nominal. It will be seen that the falling off under wheat and rice was in a measure made up by the wheat and rice lands being brought under cultivation of "other food grains," the result partly of rotation, and partly of the peculiar features of the season.—*Delhi Gazette.*

SELECTIONS.

AGRICULTURAL REFORM.

THE last *N.-W. P. Gazette* contains some interesting papers about the management of a certain property called the Awa Estate, now in the hands of the Court of Wards. The detailed account of what has been done is set forth in a note by Mr. Buck, but this enters too fully into the *minutiæ* of agricultural management to be acceptable to the general reader. We pass on, therefore, to certain remarks by Mr. A. O. Hume, the Junior Member of the Board of Revenue, on the general principles involved. Mr. Hume, after praising the contents of the note, says :—

It is no small additional merit, I may add, that it incidentally exhibits in the clearest light the *raison d' être* of the Agricultural Department of the North-Western Provinces, and quite unconsciously, though triumphantly, vindicates this from the thoughtless strictures to which it has in recent times not unfrequently been subjected.

No encomiums, however eloquent, could speak so highly for this as do the glimpses we are here afforded of the department *at work*, of the nature of the difficulties with which it is grappling, and of the spirit in which it encounters them.

Strange as it may appear at the present epoch, opinion, even amongst experienced officials, still seems to be far from unanimous as to the feasibility of effecting any appreciable improvement in Indian agriculture; and officers even in the highest positions are found, who not only express doubts as to the success of any possible attempts in this direction, but who actually, pre-judging the question, unhesitatingly condemn these as an unjustifiable waste of money!

On the other hand, there are many and indeed, I believe a daily increasing majority, who not only hold it to be our plain duty, alike to the people and to the State to make these attempts, but who entertain no shadow of doubt as to their inevitable ultimate success, if only they be guided by knowledge and conducted with sound judgment.

To me, therefore, it is most gratifying to have thus an opportunity of showing, as it were in practice, the kind of measures that we believe to be likely to prove beneficial, and the manner in which we think that these should be approached.

True, Awa is but a tiny spot, a scarcely perceptible speck on our vast empire; but it is none the less fairly typical, as regards soil, climate, population, and agricultural conditions generally, of more than half of the North-West Provinces (to say nothing of other parts of the country); and the tentative measures now (and hereafter, as experience is gained *to be*) proposed for Awa, will be equally applicable to enormous tracts yielding a land revenue of several millions sterling. Any successes here achieved will have been virtually established for this entire area; and as for the method, there can be only one true method; and if we are correct in this here, it is applicable to the whole empire.

It is true, Mr. Hume goes on to say, that—

We cannot *force* civilization, or any of her handmaids, on any people; but it is possible, by patience and tact, if we do ourselves possess the knowledge, so to put before all we deal with, good and evil in any matter, that many shall inevitably choose the good: and this is all that our supposed State intervention in agriculture has ever aimed at. We advocate no system of State agriculture, we do not propose to cultivate the people's land for them, but only by careful study of local conditions, and by the application, with suitable modifications, of methods thoroughly approved elsewhere, to evolve improvements in the indigenous practice; and so put these before all interested in such questions, that they may realize their full scope and verify them for themselves.

If this be not an appropriate and legitimate undertaking for the more enlightened rulers of a less enlightened nation, we must abandon all scientific conceptions of the functions of a Government thus situated.

As for those, if there be any such who honestly disbelieve the possibility of material improvement, and who are ignorant of the thoroughly verified fact that, with improved agriculture (using the word in its widest signification), the great bulk of the land can be made to (and *does* wherever it has been fairly tried) yield from 30 to 70 per cent. more than it now does, no *argument* (which postulates a knowledge of facts on both sides) is possible, and we can only urge them to acquire at least some rudimentary acquaintance with the subjects on which they pass judgment.

Now these proposals of Mr. Buck's appear to me on the whole to illustrate very happily *not only* the kind of measures which we may even now, despite our imperfect knowledge, take in hand cautiously, but also the manner and spirit in which they should be attempted, and the nature of inquires that should precede and accompany them, both as a security for the steps we are actually taking and as a means to future further progress.

In the first place, we have the Director of Agriculture working with and through the local civil officer and in perfect harmony—both (and I speak advisedly, having visited Awa, and having discussed all these questions with them on the spots) subordinating all other feelings to a desire to do good to the people. Joined with the civil officer, by the good offices of the Director, we have an accomplished engineer officer (to whom already the Department of Agriculture, to which Government has attached him, is no little indebted), thoroughly imbued with the Director's view and aims at co-operating in all the civil officer's plans for giving effect to these.

Then, we have a trained native agriculturist, a mere farm labourer a few years ago, now a well qualified practical teacher, who had elsewhere adopted, from conviction on his own land, the improvement he has now to set before the Awa ryots. Lastly, a native officer thoroughly *au fait* at this class of work, collecting amongst the people these multitudinous details of local usage, a knowledge of which is essential, if we are to advance (it may be slowly, but) surely.

No large crude projects are suggested, only the tentative introduction, on a scale sufficiently large to form a safe basis for future operations, of measures which either from their nature or from trials on a smaller scale elsewhere must, we know, unless (as is always possible) some special local conditions interfere, prove more or less a success.

As is right and necessary at this stage of the operations, the proposals refer almost more to inquiries that have to be carried on, and problems that have to be solved as a preliminary to future work, than to work that is to be carried out at once.

Compared with the huge rental of the estate, the expenditure proposed is moderate, and it is of such a nature that even though it may not effect all that is hoped for no material portion of it can be altogether lost; and, taking it as a whole, we may safely predicate that the State will have had the worth of its money either directly or indirectly through its tenants.

It is satisfactory to find that the local Government is heartily sympathetic with the good work thus reviewed. A Secretariat note, under cover of which the papers are now issued, says :—

As to the general question if there be any who doubt that the indigenous agriculture of this country is susceptible of vast improvement, or that to secure this improvement is one, at least, of the most important objects that any Government in India can set before it, Sir George Couper is not amongst the number. On the contrary, he attaches much importance to this work, and heartily endorses all that the Junior Member urges as to the value of the embryo Agricultural Department of these provinces and the energy and zeal of its Director, Mr. Buck. If either are anywhere misunderstood or depreciated it is not in these provinces where they are necessarily best known, nor by the Lieutenant-Governor who may be presumed to be at least as well placed as any one else for forming a correct opinion. Alike in their failures and in their incipient successes, his Honor believes that they have done excellent work, and in some at any rate of the right directions, and he has no doubt that most of what has been expended on and by them has been profitably spent, and will ultimately—in the results for which the way is being thus prepared—prove to have been wisely invested.

OSIER PLANTATIONS.

FROM their valuable economic properties, willow and osier plantation should form a very important feature in many districts, both at home and in the colonies, which are at present entirely neglected, or planted with much less remunerative crops. There are several varieties of willows or osier which, from their various properties, are deserving of more general attention than they at present receive. About 7,000 acres of land in England are devoted to the culture of willows for basket-making purposes, and, in addition to the produce of these plantations, over 5,000 tons of willow stems, valued at £10 a ton, are imported into this country, to be manufactured into baskets, besides ready-made baskets to an equal value. Land, comparatively valueless for grain or other crops, will produce a thriving crop of osiers, the principal care being that wet undrained land should be planted with those hard-wooded varieties, such as *salix caprea*, *S. alba*, and *S. Humboldtiana*, which produce wood suitable for axe-handles, barrel-staves, &c.; while light dry soil should be devoted to the growth of the species more particularly adapted to basket-making purposes. In addition to this value of their produce, the different kinds of willow have

special qualities which render them of great importance in agricultural operations. The length of their roots enables them to bind together, in a remarkable manner, river banks, or shifting ground on banks and slopes, whether natural or artificial; they form also tall, thick, almost impenetrable and uninflammable screens—excellent protection for cattle, or for delicate shrubs; *S. purpurea* especially is available as a hedge for game preserves, the bitter flavour of the leaves preventing rabbits or cattle from eating it. The young shoots of other kinds, on the other hand, as *S. daphnoides* and *S. tetrasperma*, form excellent cattle fodder; the flowers of *S. caprea* are eagerly sought after by bees, while *S. fragilis* and *S. alba* contain an abundance of tannin, excelling the oak in this respect, and, at the same time, are rich in salicine (a valuable anti-rheumatic substitute for quinine). This enumeration of some of the virtues of the osier should encourage its cultivation in the colonies, in most of which it will thrive exceedingly, as well as at home.

Osier willow for basket-making grows luxuriantly in Tasmania wherever the thrifty farmer fills up his waste corners with it.

We publish from Baron Mueller's excellent work "Select Plants Readily Eligible for Industrial Culture," a digested account of the various species of willow, which points out their special qualities :—

Salix alba (Linné). The Huntingdon or silky willow of Europe, originally probably from Middle Asia. Available for wet places not otherwise utilised. Height eighty feet, circumference of stem twenty feet; wood light and elastic, available for carpenter's work and implements, bark for tanning. The golden osier *Salix vitellina* (L.), is a variety. The shoots are used for hoops and wickerwork. With other large willows and poplars one of the best scavengers for back yards, where drainage cannot readily be applied; highly valuable also for forming lines along narrow watercourses or valleys in forests, to stay bush-fires. The charcoal excellent for gunpowder. The wood in demand for matches.

Salix Babylonica (Tournefort). The weeping willow, indigenous in West Asia as far as Japan, sparingly wild, according to Stewart, in the Himalayas, probably also in Persia, Kurdisan, and China. One of the most grateful of all trees for the facility of its culture, rapidity of growth, and fitness for embellishments, also as one of the quickest growing and most easily reared of all shade-trees. Dr. C. Koch distinguishes another weeping willow as *S. elegantissima* from Japan. Important for consolidating river-banks.

Salix Capensis (Thunberg), *S. Gariepina* (Burchell), South Africa. This willow might be introduced on account of its resemblance to the ordinary weeping willow. *S. daphnoides* (Vill.) of Europe and Asia, *S. petiolaris* (Smith), *S. cordata* (Muehlenb.), *S. tristis* (Ait.), of North America, are among the best for binding sand. *S. longifolia* (Muehlenb.), also North American, is among those which form long flexible withes.

Salix caprea (Linné), Europe, North and Middle Asia. The British sallow or hedge willow; grows also to a tree; wood useful for handles and other implements, the shoots for hoops. It is largely employed for charcoal for gunpowder. Bark for tanning, particularly glove-leather. The flowers are eagerly sought by bees. It is the earliest flowering willow.

Salix cordata (Muehlenberg). One of the osiers of North America.

Salix daphnoides (Villars). Middle Europe and Northern Asia, as far as the Amoor, ascending to 15,000 feet in the Himalayas. A tree of sixty feet in height, of remarkable rapidity of growth, attaining twelve feet in four years. It is much chosen to fix the ground at railway embankments, on sandy ridges and slopes, for which purpose its long spreading and strong roots render it particularly fit. The twigs can be used for baskets and wickerwork and twigbridges (Stewart and Brandis). The foliage furnishes cattle fodder. The tree is comparatively rich in salicine, like *S. pentandra* (L.)

Salix fragilis (Linné). The crack willow. Indigenous in South-Western Asia. Height, ninety feet stem, to twenty feet in girth. A variety of this species is the Bedford willow, *Salix Russelliana* (Smith), which yields a light elastic tough timber, more tannin in its bark than oak, and more salicine than most congeners. One of the dwarf American willows perhaps *S. tristis* (Aiton), has been traced on the coast sands of California to send out root-like stems up to 120 feet length.

Salix Humboldtiana (Willdenow). Through a great part of South America. This willow is of pyramidal habit, attains a height of fifty feet and more. The wood is much in use for yokes and other implements. Many kinds of willow can be grown for consolidating shifting sand ridges.

Salix lucida (Muehlenberg). One of the osiers of North America.

Salix nigra (Marshall), *S. Purshiana* (Sprengel). The black willow of North America. It attains a height of twenty-five feet. The black willow is one used for basket-work, although it is surpassed in excellence by some other species, and is more important as a timber willow. Mr. W. Scaling, of Basford, includes it among the sorts, which he recommends in his valuable publication *The Willow* (London, 1871).

Salix purpurea (Linné). Of wide range in Europe and West Asia. One of the osiers. In deep moist soil, not readily otherwise utilised, it will yield annually four to five tons of the best of rods, qualified for the finest work. Impenetrable, not readily inflammable; screens twenty-five feet high can be reared from it in five years. In localities exposed to storm willow-screens fully forty feet high can be raised. It is invaluable also for the reclamation of land along watercourses. Rich in salicine. From Mr. Scaling's treatise on *The Willow*, resting on unrivalled experience, it will be observed, that he anew urges the adoption of the bitter willow (also called the rose willow or the whipcord willow), *S. purpurea* (L.), for game-proof hedges, this species scarcely ever being touched by cattle, rabbits, and other herbivorous animals. Not only for this reason, but also for its very rapid growth and remunerative yield of the very best of basket material he recommends it for field hedges. Cuttings are planted only half-a-foot apart, and must be entirely pushed into the ground. The annual produce from such a hedge is worth 4*s*. to 5*s*. for the chain. For additional strength the shoots can be interwoven. In rich bottoms they will grow from seven feet to thirteen feet in a year. The supply of basket material from this species has fallen very far short of the demand in England. The plant grows vigorously on light soil or warp land, but not on clay. *S. rubra* (Huds.) is also admirably adapted for hedges. The real osier *S. viminalis* (L.), is distinguished by basket-makers as the soft-wooded willow, and is the best for rods requiring two years' age, and also the most eligible for hoops, but inferior to several other species for basket manufacture. *S. triandra* (L.) is a prominent representative of the hard-wooded basket-willows, and comprises some of the finest varieties in use by the manufacturers. A crop in the third year after planting from an acre weighs about twelve tons, worth £3 for the ton. *S. fragilis* (L.) and *S. alba* (L.) are more important as timber willows, and for growing hoop shoots. Their rapidity of growth recommends them also for shelter plantations, to which advantage may be added their uninflammability and their easy propagation; the latter quality they share with most willows. Mr. Scaling's renewed advocacy for the formation of willow plantations come with so much force, that his advice is here given though condensed in a few words. Osier plantations come into full bearing already in the third year; they bear for ten years and then slowly decline. The raw produce from an acre in a year averages 6 tons to 7½ tons, ranging in price from £2 10*s*. to £3 10*s*. for the ton (unpeeled). Although 7,000 acres are devoted in Britain to the culture of basket willows (exclusive of spinneys and plantations for the farmers' own use), yet in 1866 there had to be imported from the continent 4,400 tons of willow branches, at a value of £44,000, while besides the value of the made baskets imported in that year was equal to the above sum. Land comparatively valueless for root or grain crops can be used very remuneratively for osier plantations. The soft-wooded willows like to grow in damper ground than the hard-wooded species. The best peeled willow branches fetch as much as £25 for the ton. Peeling is best effected by steam, by which means the material is also increased in durability. No basket willow will thrive in stagnant water. Osier plantations in humid places should therefore be drained. The cuttings are best taken from branches one or two years old, and are to be planted as close as one foot by one-and-a-half foot. No part of the cutting must remain uncovered, in order that only straight shoots may be obtained; manuring and ploughing between the rows is thus also facilitated, after the crop has been gathered, and this, according to the approved Belgian method, must be done by cutting the shoots close to the ground after the fall of the leaves.

Salix rubra (Hudson). Throughout Europe, also in West Asia and North Africa, it is much chosen for osier beds. When cut down, it will make shoots eight feet long in a season. Porcher regards it as one of the most valuable species for work in which unpeeled rods are used.

Salix tetrasperma (Roxburgh). Mountains of India, from 2,000 to 7,000 feet. Height of tree forty feet. This thick-stemmed willow is worthy of a place on the banks of our watercourses. The twigs can be worked into baskets, the wood serves for gunpowder, the foliage for cattle food.

Salix triandra (Linné). *S. amygdalina* (Linné). The almond willow through nearly all Europe and extra-tropical Asia. Height of tree thirty feet. Shoots nine feet long, for hoops and white basket-work, being pliant and durable. The bark contains a good deal of salicine. *S. lanceolata* (Smith) is a hybrid between *S. triandra* and *S. viminalis*, according to Andersson.

Salix viminalis (Linné) The common osier of Europe and North and West Asia; attains the height of thirty feet. One of the best for wicker-work and hoops; when cut it shoots up to a length of twelve feet. It would lead too far to enumerate even all the more important willows on this occasion. Professor Andersson, of Stockholm, admits 158 species. Besides these, numerous hybrids exist. Many of the taller of these willows could, Baron Mueller considers, be grown to advantage in Victoria.—*Journal of Applied Science.*

THE MADRAS AGRICULTURAL DEPARTMENT.

THOSE, who are interested in the cause of agricultural reform in India, should carefully watch the working of the Agricultural Department in the Madras Presidency, under its able head, Mr. W. R. Robertson. That department consists of two branches—the Sydapet Experiment Farm and the School of Agriculture. Mr. Robertson's report on these instructions for the year ending 31st March 1878, is so interesting that we cannot resist the temptation of reviewing it, even though several months have elapsed since its publication. The report is one of the most important official documents we have for some time seen; and it retains its interest quite unimpaired to this day. We will first notice the working of the Sydapet Experimental Farm during the year under review. The year was not, on the whole, a propitious one for agricultural experiments; yet Mr. Robertson and his staff did their best to achieve successful results. Special experiments to test the value of rotation of crops were made; and we are

told that another rotation will be tried. Mr. Robertson makes the following remarks on deep ploughing:—"Deep-ploughing, that is the inversion of the soil to a great depth, is in many cases injurious, and I would warn any one from rashly attempting the practice; it has in some cases been known to ruin good land for many years, owing to a raw subsoil, in which nothing would grow, being brought to the surface. Deep cultivation, on the other hand, has almost always most beneficial effects; it is not so much that the outturn is enhanced, but that the soil is not so easily affected by climatic disturbances, and affords a larger field for the roots of plants to search for food in thus maintaining the average of productive power for a much longer period. Unless more manure is used, no extra depth of cultivation can ever permanently maintain an increased outturn, the two things must go together. No doubt under exceptional circumstances, * * * * deep cultivation gives most astonishing results in the shape of increased outturn, but had it not been for the drought the benefits would not in that case have been so easily discoverable. *I can only reiterate an opinion I have long held, that deep cultivation can, if universally followed and efficiently performed, do perhaps more to avert famine in India than almost anything else. It would also, if adopted, greatly enchance the producing capacity of this country, for our surface soils cannot but be in a very reduced condition for the supply of the requisite plant food for our crops, and very much poorer than their subsoils.*" The italics are ours. The great value of deep culture in resisting the effects of drought was possibly brought out in the Sydapet Experimental Farm during the year under review; and those who doubt the efficacy of this operation should study Mr. Robertson's report. Deep ploughing may prove injurious in the deltaic districts of Lower Bengal; where in many places sowing has to be effected by throwing the seed broadcast, but the case is widely different with the other parts of this continent. As deep culture of the soil can resist the effect of drought which is of frequent occurrence in this country, and effectually avert the exhaustion of the soil, simply invaluable.

Equally important are Mr. Robertson's remarks on the use of manures. He—writes:——Manuring is carried on either to enhance or preserve the natural fertility of the soil and the substances applied as manures all act either mechanically or chemically. It is well known that a crop grown on the land extracts from it certain mineral and nitrogenous substances required for its nutriment, and if the crop be permanently removed from the land, the amount of such substances contained in the produce is lost to it. The capacity of the soil for furnishing plant-food being limited, in the end, if cropping without returning any thing to the soil, as is usually practised on the unirrigated lands of this presidency, be continued, exhaustion must ensue. It has been abundantly proved however by Messrs. Lawes and Gilbert, at Rothstead, that, when a soil is left unmanured for some years and at the same time cropped, the annual productive power of it is reduced to so low a figure that ultimate exhaustion may be deferred for a very great length of time. The soil thus, as it were, possessed a power of protecting itself from the rapacious greed of the cultivator, for although it may contain abundance of the elements necessary for the support of plant life, these being in a presently unavailable condition, are only yielded up slowly in driblets as they become soluble." Important manuring experiments were made at the Sydapet Experimental Farm during the year under review, the results of which are fully recorded in Mr. Robertson's report before us. We notice that of all kinds of manures, saltpetre gave by far the best results; the lowest yield was given where castor-seed husks had been applied. The experiments, observes Mr. Robertson, require to be repeated and amplified before the full value of the results obtained during the year under report can be appreciated. Saltpetre has however been shewn to be a very valuable manure for cereals. In the Madras Presidency the practice of manuring is confined almost entirely to the garden land and this, we believe is more or less the case with the other provinces. The cultivator cannot afford to manure the ordinary crop as he must use for fuel the manurial substances at his command such as cattle dung, leaves of trees, &c., &c., The report before us deals at some length with exhaustion of the soil. "This," it is remarked, "is the natural sequence to the want of attention on the part of the ryot, either through ignorance or otherwise, to the laws of plant-life. It is, however, absurd to suppose that, except in the case of land newly brought under cultivation or which has not been arable for more than a few years, a short personal experience could note any signs of greatly decreased productive power. When soils are reduced to a certain rate of production, it has been found that the time of their ultimate exhaustion will be deferred for a great length of time, owing to the supplies of plant-food in them, when it has been cropped successively for some years without manure, not existing in an immediately available form, these matters are in fact inert, and are only brought into a form in which they can be made use of very slowly; and by the amount annually rendered available for the nourishment of the crops is the productive power of the soil limited. It must be remembered that land may become exhausted for profitable culture under a bad system of husbandry, and be unfitted for ordinary farming, until a large expenditure has been incurred, but still may be able to afford such scanty returns as those with which many ryots are contented. Soils when reduced to such a starving condition feel the difference of seasons, good and bad far more than those which are in a high state of fertility. These facts have been proved conclusively in England and elsewhere." The popular belief in the exhaustion of the soil, it is pointed out, is very strong in Madras; and we believe the same is the case throughout Behar and the Upper Provinces. The ryot in Madras gets 70 or 80 pounds of clean cotton per acre, whereas the American farmer is not contented unless he gets from 450 to 500 pounds per acre. The average yield of rice per acre in Madras is about 15 bushels per acre; but in America 70 bushels per acre is no unusual crop. In Madras a maize crop of 11 bushels an acre would be considered a good one, while in America the yield of this crop varies from 50 to 80 bushels and some times even amounts to 100 bushels per acre. This is the difference between a scientific and a non-scientific system of tillage. But as we have shewn in these columns in our review of Mr. Allan Hume's *Agricultural Reform* in India, the ordinary ryot cannot be expected to adopt a scientific system of agriculture, which must necessarily require the outlay of capital.—*Hindoo Patriot.*

THE WHEAT PRODUCTION AND TRADE OF INDIA.

In our former paper, we but superficially dealt with this important trade. Reserving our remarks simply to the average yields of the different provinces. This time the subject embraces not only the aggregate yields of the entire empire; but we shall make some attempt to give particulars which without doubt, will be as entertaining as they are instructive.

In a former issue we detailed the outturn of the different wheat-producing tracts in their respective orders; omitting only those provinces where the outturn was of not sufficient importance to merit its being named. We have thus been enabled to form a general estimate of the wheat wealth of the entire Empire. And for the sake of easier reference, we enumerate the districts with their returns in round numbers.

Province.	Wheat area in acres.	Estimated outturn in quarters of 480lb. or 6 maunds.
Madras	22,000	... 22,000
Mysore	12,500	... 6,800
Bengal	1,100,000	... 1,650,000
Central Provinces	3,515,800	... 3,515,800
Berar	537,800	... 273,400
Bombay	1,033,200	... 781,500
Sind	340,300	... 462,100
Ajmir	16,200	... 19,700
N.-W. P. and Oudh... ...	6,081,400	... 8,750,000
Punjab	6,070,200	... 11,116,700
Total ...	19,329,200	26,548,000

In general terms 19⅓ millions of acres are under wheat and yield 26½ million quarters. Dr. Forbes Watson's estimate of 35 million quarters, exclusive of Native States "thus appears to be too high." The area under wheat cultivation in India, is about six times as great as that of England. In 1878 Great Britain had 3,218,417 acres under this crop. According to the same authority, India stands fourth in point of production. The United States, France, and Russia taking precedence. The Punjab, North-Western Provinces, and Oudh, Central Provinces, Bengal, and Bombay Presidency, including Sind produce most wheat. And it is in the above order, that the provinces stand in point of production. It is interesting to note that the further north wheat is cultivated the larger its yield in grain. In the Central Provinces, the North-Western Provinces and Oudh, and the Punjab, the accepted average yields per acre stands at 8 bushels, 11½ bushels, and 13½ bushels respectively.

Latitude, however, has but little to do with the crop. More depends upon cultivation, the use of manure and irrigation. Irrigation is everything in India; yet it is extremely difficult to give an accurate estimate as to the yield of wheat on irrigated and unirrigated lands. The crop requires moisture, and on unirrigated lands is entirely dependent to the amount of rainfall. It would be idle to deny that irrigation does not improve the yield. For in Nasik, where the experiment was tried, showed that the yield was more than trebled; whilst in Surat it increased by only 50 per cent. There is very little wheat under canal irrigation in Bombay. About 4,957 acres out of a total of 24,536 acres. In Sind, where the yield is far higher, the wheat fields are moistened either by floods or percolation. This is accounted for by the cultivation being chiefly on the alluvial lands of the Indus.

The same conditions prevail in Bengal. In Orissa there is scarcely any wheat cultivation. Artificial irrigation is extremely rare in the Central Provinces. Though some attempt is made to preserve the rain water by embanking the fields. Canal irrigation in these provinces, as well as the Punjab, is in fact a *sine qua non*.

In the North-West Provinces during the year 1877-78, there was a total of 1,461,429 acres under canal irrigation, and of this amount wheat took up 415,793 acres.

And in the Punjab for the same year there were 1,318,026 acres under canal irrigation, of which 342,619 acres are perennial, and 105,195 innundation.*

* Perennial canals are those which are able to irrigate lands all the year round, whilst the inundation canals (which are numerous in Punjab and Sind) are flooded during the rains and can only then be made of use, as they are perfectly dry nine months out of the twelve.

So the average area for five years in the North-West is 453,842 acres, and in the Punjab, including the inundation canals, 881,556 acres. As a rough approximation it may be assumed that the yield per acre in the Punjab of unirrigated lands is between 7 and 8 maunds; of lands irrigated by canals 12 maunds, of land from wells 13 maunds, and of lands irrigated by other means, such as hill streams and natural drainage, 9 maunds. Accepting this classification as correct; we have the following statistics regarding wheat irrigation. It must be borne in mind that the Punjab is the only province for which such figures are available.

	Acres.
Wheat irrigated from	
„ „ wells	1,600,000
„ „ canals	381,000
„ „ other works not under Canal Department.	426,000
Wheat unirrigated, ...	4,262,413
Total ...	6,670,000

The yields abovementioned, do not give so high an average as 10 maunds per acre. It must be remembered that a fairly high rate is maintained where the sub-montane tracts have a good rainfall. Whilst in the Multan and Derajat divisions, wheat is, and only can be, cultivated on lands irrigated from canals, surface drainage and hill streams. In these provinces wherever it is possible, irrigation is resorted to; in Bundelkhund the presence of sufficient natural moisture renders it unnecessary. It is "remarked that the extension of canal irrigation has led to a wider cultivation of wheat without a corresponding increase in the manure supply."

It is in the Punjab that the question of irrigation is of such vital moment in connection with wheat cultivation. The total area of this province is 104,975 square miles, of which 35,377 only are cultivated, 30,981 culturable, and 38,617 unculturable waste. There are 9,182,313 acres of culturable waste, the property of Government.

It is not then surprising that under these conditions canal projects have been entertained, estimated to irrigate a million acres for the spring crop.

Owing to financial pressure these canals exist as yet only on paper. But two canals are now under construction—the Sirhind and Swat canals. The first will irrigate 783,000 acres; and the second 120,000 acres. Here the report indulges in a delicious vista of land actually flowing with corn and honey. For it argues that on perennial canals in the N.-W. P. and Punjab, wheat takes up about 40 per cent. of the breadth watered; why should not an additional area of wheat be given to the Sirhind canal of 313,200 acres; and only the Swat canal of 48,000 acres. And then not content, it asks might not a further addition "be made to the wheat area of at least 200,000 acres, or 561,200 acres altogether. At 12 maunds, the acre, the produce for the province, would thus be increased by 1,122,400 quarters."

We are now brought to consideration of the question, as to the likelihood of a trade ever springing up in this commodity. Up to the present, little or no hope is held out that the trade will assume any considerable proportions. "There may be some trade with Mediterranean ports; but it is the English demand which has hitherto been effectual." And this is owing to numerous circumstances. The prices of British wheat and food grains in India, the amount of English imports from Russia, the rate of exchange on India and other causes. In 1877, 305,247 tons of Indian wheat were imported to England, and the average price per quarter was 56*s.* 9*d.* in 1878, only 90,965 tons were imported and the price paid was 46*s.* 5*d.* On the whole Indian wheats are now fetching at the rate of about 39*s.* to 40*s.*

Australia and Canada have also taken the field; and if it pays these countries to export wheat to England, there is no reason why Indian wheat should not be able to compete in the home market. But a formidable competion has arisen both in the far west and in the Dominion of Canada; and it will be a long day before India will be able to produce as much wheat as the American virgin tracts are supposed to be capable of doing.—*Indian Herald.*

INDUSTRIES OF INDIA.

COTTON: ITS COMMERCIAL HISTORY.

WE have shown in a former article how very early the Hindoos acquired the art of making cotton fabrics of various kinds from the cotton plant, its uses being well known to them, when other countries were quite in the dark even as to its very existence. Primitive, though their processes were, from the cleaning of the cotton to its conversion into those beautifully fine muslins described as "webs of woven wind," they were effectual, and for the results of their labours the Indian natives were justly celebrated all over the known world. They had no implements, with the exception of their hand-looms, worthy the name of machinery, and prior to the invention of these hand-looms for weaving, used only their fingers and the spinning wheel. Yarn they spun on the distaff, and the patient and practised Indian spinner by the wonderful and careful manipulation of finger and thumb in the formation of the thread, which acquired just the proper degree of moisture by passing through his hands, produced fabrics of surpassing fineness, unequalled indeed, until quite recently, by any machine-aided efforts.

An Indian loom consists of merely a few sticks and reeds, which stock-in-trade the humble possessor carries with him from place to place, so that he is ready at any time to fix it up and begin to work. He chooses usually a shady tree under which he can sit, digs a hole deep enough to hold his legs, and the lower part of the *gear*; the balances being fastened to the branches of the tree above his head; underneath the frame he makes loops into which he places his great toes (the natives are quite as clever with their feet as with their hands); these serve as treadles, and his shuttle, which is merely an enlarged netting needle, he uses as a *batoon.* A loom of this sort has no beam, and the warp is laid out on the ground the whole length of the cloth. The very finest Indian muslins come from Dacca, Santipoor, Sonargа, and Vicrampoor; the price of a single piece of this very fine muslin, which takes an Indian weaver four months to produce, will sometimes amount to Rs. 400 or 500. The striped and flowered muslins of Dacca were formerly considered inimitable, and were so very much thought of and sought for by the higher classes in India, that the demand was greater than the supply. The great skill attained by Indian weavers is not difficult to account for. Weaving is an hereditary art, the same trade going down from father to son for generations. The father teaches his son while young the mysteries of his employment, and the weaver, beginning to practise his trade at an early age, soon becomes a proficient in the art, and with the most simple appliances turns out the very finest work. We write of years gone by: now, the excellence of our machinery, brought as it is to the highest perfection, has not only enabled us to complete with native hand-workmanship but to outstrip it. England has long ceased to depend on India for her fine muslins, and instead of importing such piece-goods from thence, exports them thither.

The art of manufacturing these extra fine materials has therefore languished of late years; still neither English nor Bombay mills have, so far, entirely displaced those hand-made goods which once were so famous. Formerly, Arabia, Syria, Persia, Egypt, Abyssinia, the eastern parts of Africa, besides Europe, were all supplied with muslins from India, the chief marts being Surat and Calicut on the west coasts, and Masulapatam, Madras, and St. Thome on the east coast. Now, the natives confine themselves chiefly to supplying the home market they mostly make their own clothing, common muslins being manufactured still in most of the villages. Cloth goods are also made from their home-grown produce, and the art of weaving, has by no means, died out amongst the people, though not practised to the extent it once was. Those villages removed furthest from the line of rail do the briskest trade in muslins, cloth, calicoes, and printed goods, because European competition is not so much felt in them. The natives dye their cloths red, blue, green, brown, yellow, and intermediate shades of these colours, and also decorate their cotton goods with bands of colour around the borders. Dhawar, Poona, Ahmedabad, Mulligaum, Yeola, Ahmednuggur, are all famed for their cotton goods; Surat and Ahmedabad for their 'kincobs,' which are the richest description of goods, having gold and silver threads woven into the fabric, and silk also. Long cloths and pullicats are chiefly made in the Madras Presidency; coarse spun goods and pullicats in Surat; the finest calicoes in Masulipatam; cloths resembling diaper and dimities, as well as the finest muslins, in Dacca; plain and flowered muslins in Benares; 'Baftas' are manufactured in the south-east of Bengal; 'Khasahs' to the north of the Ganges; 'Sussaes' are the chief fabric of Orissa; 'Gurraes' come from Birbhoom, and the still coarser cloth, such as 'Gezis' and 'Gezinas,' are woven in most districts, more especially in the Doab of the Ganges and Jumna. The N. Circar long-cloth is made of Berar cotton. Patna is the chief seat of the chintz manufactures, and this original art of the Indian natives is brought by them to very great perfection.

So numerous were the various fabrics produced in India, that as early as 1700, a great outcry was raised by the manufacturers of this country, who, seeing with alarm the rapidity increasing Indian export trade in piece-goods, clamoured for a check to be placed on it, as they fancied that the cheapness and quantity would undermine their own trade. In 1701, therefore, an Act of Parliament was passed to forbid Indian silks and printed calicoes for domestic use, being imported either for wearing apparel or furniture, and very heavy penalties—in some cases as much as £200—were, we learn, imposed on seller or wearer, "to avert the ruin of English manufacturers and revive their prosperity." In those days such an alarm being raised seems to us rather astonishing, for even taking into consideration the extreme cheapness of Indian labour, and the beauty and fineness of their cotton and muslin piece-goods, without mills—for there were none in India then—the Indian natives could not have stood competition with English firms, who backed up as they were by wealth and power could afford to buy up Indian cotton *raw*, ship it thousands of miles to manufacture, mix it with cotton from other countries—notably American cotton—and then send it back in piece-goods to the very country from which it originally came. In these days, however, when Indian cotton mills have increased to such an extent, and protected as their productions have been by the duties, against which so much has lately been said and written, there is far more reasonable cause for alarm; but to this subject we intend to refer later on.

Royle tells us that "cotton was first imported into England, in 1783, when about 114,133lb. were received." But as early as 1684, considerable attention was paid to the exportation of the raw material, and attempts were even then made to save the cost of freight by compressing the cotton into bales by machinery. Many and great improvements have been made in the cotton screw since that date, and such immense pressure is now brought to bear that 392lb. can be compressed into one full bale. Much of the cotton exported in the very early days of the trade was shipped not

to England, but to China. We gather from Maclean that in 1805, the exports of cotton to China were worth 64 79,689 sicca rupees (the sicca rupee being then worth 2s. 6d.), while the London exports only reached 5,88,725 sicca rupees. This trade with China was not of long duration, though, and has fallen now to less than 5 million lb., from 80 million, which it reached in the zenith of the trade.

In the first year of the Free Trade with India (1814) the raw cotton exports, to us, began to increase very considerably, and to a great extent killed the Indian export trade in piece-goods, which had caused so much alarm to British manufacturers. Each year the Indian natives became more willing to export their raw material to England, taking it back again when mixed with American produce in the form of piece-goods, differing from the fabrics they themselves produced in texture and in price. In 1793 American cotton began to be in good request, and as the exports from that country rapidly increased, the demand for East Indian cotton to mix with, is increased also. Between the years 1814 and 1846 various fluctuations both in prices and quality of exported raw material, took place in both India and America; failures in Calcutta in 1830, increase in the prices of American upland cotton in 1836, the Chinese war in 1839, the distress in the home manufacturing districts in 1840 continuing through 1841, the peace with China in 1842, and the increasing prosperity at home in 1845, all contributed to cause these ups and downs in the trade.

The lowering of the price of American cotton caused the marked falling off in the East Indian cotton exports in 1848; they, however, revived in the following year when American produce fell short; and when the American war broke out in 1861, and between that year and 1865. when our supply from America was cut off, then indeed were halcyon days for Indian exporters, and Maclean puts the average value of the cotton exports for those five years at a yearly average of £21,582,847 for Bombay alone. Then began those speculations which ended so disastrously in the "Bombay panic." Companies of all sorts and kinds were formed, joint stock, banks, financial associations, and land companies. But when the American war ended, then came the total collapse of those Bombay speculators who had "plunged" so wildly. By the end of 1866 the financial associations had failed or gone into liquidation, the banks, with one or two honourable exceptions, were blotted out of existence, the land companies became insolvent, and there was one general crash. Maclean has in his "Guide to Bombay" a very interesting account of that city during this season of panic and confusion. As Bombay had had the chief benefit of the wonderful increase of the cotton export trade during the years mentioned, by which some seventy-five millions sterling came into her coffers and gave her the speculation fever, so was she the chief loser by those suicidal undertakings into which the sudden accession of such a vast sum had hurried her.

This panic did not, however, affect her permanently, for in 1874-75 her cotton exports had increased from 34 to 50 million pounds, and the monetary value from 9½ to 12½ millions sterling.

The cotton mills of Bombay, the first of which was started in 1854, have made, since that date, very rapid progress. We find no less than 41 spinning and weaving mills in the Bombay Presidency at work, and more in the course of erection, while in Calcutta there are 5, 2 in Madras, 2 at Cawnpore, 1 at Nagpore, 1 at Indore, and 1 at Hyderabad in the Deccan, or 53 in all India. These mills give work to 10,533 looms and 1,289,706 spindles, and are nearly all conducted under skilled European supervision. There is to each mill a manager, weaving master, spinning and carding master, and an engineer. The mills are further managed by a Chairman and Board of Directors, with the assistance of a Secretary, there also being an agent. The latter's work is most important; he purchases the cotton, the coal for working the engines, the stores needed, and all other necessaries, arranging moreover the sale of the cloth and yarns. Skilled English labour commands a high price, from Rs. 200 to 400 per month, sometimes running as high as Rs. 500. In some few mills the managers are natives, and before long this will be the case in many more instances, for young natives are now very frequently found serving an apprenticeship in large cotton mills, with a view to qualifying themselves for the posts of managers at some future period. Indian labour is however, as yet far inferior to English, the rate of pay is lower, and therefore the work is done more cheaply, but a native's *physique* is far below an Englishman's, and he is not equal to the same amount of sustained work.

The following extract from "Maclean's Guide to Bombay" will be found of interest:—"A middle-sized mill, say of fifteen lakhs, having 80,000 spindles and 600 looms, employs on an average 1,000 people; whereof 100 or thereabouts are boys and girls, 100 women, and 800 male adults. The hours of work are from 6 A.M, to 6 P.M., with an hour for recess in the middle of the day for meals and smoking. Nearly every mill has a smoking-shed. Fresh Vehar-water is freely supplied to all operatives, and generally they are all well cared for, much better than work-people employed in other industries in Bombay. The average wages earned by the various mill operatives are as follows:—

For each boy or girl	...	... 5 rupees per month.
" " female	...	... 8 " "
" " male	...	... 16 " "

The head jobbers earn as much as Rs. 70 and 80 a month. On an average a mill of the description named above, that is, one having 30,000 spindles and 600 looms, would consume per mouth—cotton, 238,000 lb; coal, 286 tons; stores and other articles worth Rs. 8,000 and would pay wages to labourers amounting in round numbers to Rs. 12,000. It would produce 20,000 lb of yarn, and 209,000 lbs. of cloth per month.

The treatment of the Indian operatives in cotton mills has recently been brought before the public. Certainly the factory rules and regulations in India stand in need of much amendment, the hours being too long particularly for women and children, and the latter being employed to work in mills at too early an age. This, however, is scarcely a question to be dwelt on here, when the commercial history of the Indian cotton trade is the subject of consideration; we must therefore leave it in the hands of those who have agitated, we hope with success, for the amendment of the Factory Acts in India, and considering that some 40,000 natives are employed in Indian factories, it is none too early to investigate more thoroughly, and strive as far as possible, to ameliorate their present condition by regulating their hours of labour and of recreation, and restricting the age for children commencing work to eight: instances having been given in which mere infants of the tender age of *five* years were set to labour hours at a time in cotton mills.

Bringing the exports of cotton down to date we find that for the last five years the exports of raw cotton have been as follows:—

	Cwts.	Rupees.
1873-74	4,499,698	13,21,22,409
1874-75	5,600,086	15,25,73,416
1875-76	5 0 9,783	13,27,89,685
1876-77	4,557,914	11,74,61,836
1877-78	3,459,077	9,38,35,340

The above figures, which are taken from Mr. O' Connor's "Review of the Trade of British India for the official year 1877-78," show plainly the downward course of the last three years. The quantity shipped to the United Kingdom has been ever since 1871-72 falling off each year, England being no longer so large a customer for Indian cotton as she once was. Austria, France, Germany, and Italy are, however, maintaining a fair demand for the article, and their yearly consumption of the Indian raw material is increasing slowly but surely, while the China trade is again looking up, she having taken some 209,000 cwt. in the year.

With regard to manufactured cotton, the following figures, taken from the same source, represent the value of cotton twist and piece-goods exported by India to foreign countries during the last five years:—

	Rupees
1873-74	52,26,298
1874-75	51,23,742
1875-76	66,34,236
1876-77	81,23,822
1877-78	1,14,27,323

"At first sight," Mr. O'Connor says, "these figures, as showing that the trade has doubled itself in five years, would be taken as a gratifying indication of the flourishing condition of the cotton, spinning, and weaving industry in India." He goes on to show that such, however, is not the case, the Indian cotton mills having had in recent years much to contend against. Over-production in Lancashire, which glutted the Indian market with Manchester stock, and the failure of crops, which was caused by drought, impairing the purchasing power of the people, are the two chief causes of the trade being unfavourable to the Indian mills; the increase noticeable in the exports being accounted for by the fact that the mills having accumulated large stocks, were obliged to get rid of them at considerable loss in point of value, the exports being increased really by sacrifice of goods.

This increased export is, however, again exercising the alarms of British manufacturers. The *raison d'être* of these renewed fears on the score of Indian competition must be reserved for future consideration.—*British Mercantile Gazette.*

VISIT OF DR. KING TO JAVA.

No 96C, dated Royal Botanical Garden, Howrah, the 22nd November 1879.

From—GEORGE KING, ESQ., M B., Superintendent, Royal Botanical Garden, Calcutta, and in charge of Cinchona Cultivation in Bengal,

To—The Secretary to the Government of Bengal, Revenue Department.

IN accordance with the orders of Government, marginally noted, I proceeded in August last to Java to inspect the cinchona plantations of the Dutch. Government is aware that, although it is from the species known as calisaya that the most valuable of all the medicinal cinchona barks are obtained, the cultivation of this sort has not hitherto been so successfully prosecuted in British Sikkim as has that of cinchona succirubra. Cinchona calisaya is found to be in Sikkim (as has been explained in several of my annual reports) a very variable species, and its variations are not confined to the form of leaves and flowers, but extend also to the chemical constitution of the bark, that of some of the varieties grown in Sikkim containing nearly eight per cent., of pure quinine, while the bark of others yields very little of quinine, or of any other useful alkaloid. But the differences in external form and of richness in alkaloid are not related to each other in any very difinite way, and trees of which the leaves and flowers are so much alike as to be undistin-

Government of Bengal, Financial Department, Agriculture docket No. 39 dated 19th February 18 9, forwarding copy of Government of India, Department of Revenue, Agriculture, and Commerce, No. 47, dated 10th February 1879.

guishable from dried specimens have been found to yield bark of quite different chemical composition. It had for some time been known from the official reports on their plantations in Java, that the Dutch have in cultivation there, a variety of calisaya, the bark of which is richer in quinine than any bark ever imported from South America; some of the Dutch samples having yielded on analysis the extraordinary amount of 13·7 per cent. of quinine. The object of my visit was to see exactly what this variety is, and by spending some time in the plantation, to learn what the conditions are under which it has been so successfully cultivated. Before leaving India I was furnished with a letter of introduction from his Excellency the Viceroy, to the Governor-General of Netherlands India, and I have to acknowledge the courtesy and kindness which I received from the Dutch authorities by whom every facility was afforded to me for travelling in Java and for inspecting the Government plantations.

2. The cinchona plantations of the Dutch Government do not, as in Sikkim, form a compact belt, but consist of seven distinct and separate estate scattered over a range of volcanic hills in the centre of the island. These estates range in altitude between 4,000 and 6,400 feet above the sea-level. In all of them the soil is of a dark-brown colour, light and friable, very pervious to water, and almost free from stones. The surface soil is uniform and in general deep (in some places it reaches a depth of 12 to 14 feet), and is rich in vegetable matter. The sub-soil is lighter in colour from the absence of humus, but has similar physical properties. Both surface and sub-soil have as their basis decomposed trachytic rock rich in potash, and they were recognised by Hochstetter (an eminent German geologist familiar with the volcanic regions of the Andes and who recently visited Java) as almost identical with the Andesite formation of the Cordillera on which cinchona is indigenous. The slopes of the hills, on which the plantations stand are so very gentle that washing of soil is very slight and landslips are almost unknown. The drainage water finds its way underground to the larger streams which separate the ridges. The absence of small superficial drainage channels is quite a feature in the country and illustrates well the great permeability of the strata. The natural vegetation in these hills is very like that at a slightly lower elevation in Sikkim. The climate is, however, greatly different from that of Sikkim. At Tjinirœau (5,100 feet above the sea) the temperature at 6 A.M., all the year round rangs from 50° to 59° Fahrenheit, except during the two dry months when it occasionally falls as low as 44° Fahrenheit. The highest temperature during the day is 73·5° Fahrenheit. The mean average over the whole year is 53·5° Fahrenheit, while the constant temperature of the soil at five feet from the surface stands all the year round at 64·01° Fahrenheit. The rainfall for the year varies at the different estates from 120 to 140 inches. The rainy season *par excellence* extends from November to June. Of the remaining four months, August and September are the driest. But there are very few days absolutely without a shower in the afternoon. The rain falls at all times very gently, and violent storms and floods are very rare. It is only during the early part of the rainy season that rain falls during the early part of the day; at other times it falls chiefly in the afternoon. The climate is a remarkably even one, and the weather for the day can be predicted every morning from the temperature about sunrise. Experience at Tjinirœau (the chief Government plantation) has shown that if the thermometer at 6 o'clock A.M. stands at or below 54·6° Fahrenheit, no rain will fall during the day. If it stands at 55·4° Fahrenheit, rain in the afternoon is probable; if at 57° Fahrenheit, rain in the afternoon is certain; while if it stands at 60·8° Fahrenheit rain will surely fall before noon.

3. All this forms a strong contrast to the state of matters in Sikkim. There the basis of the soil is decayed primitive rock (gneiss and mica schist) poor in potash; the surface soil, although rich in vegetable matter, is very irregular in depth, is occasionally very stony, and is everywhere ploughed, up into small channels for the transmission of superficial drainage. The sub-soil is stiff, cold, and little permeable to water. In Sikkim the contrast between the temperature of day and night and of summer and winter is great, and the rainfall, although about of the same volume as in Java, is so distributed over the year, that while for seven months everything is saturated with moisture, during the other five hardly a shower falls from the clouds.

4. The fertility of volcanic soils is proverbial, and the partiality of the medicinal cinchonas for such soils, as well as for a cool equable climate where the rainfall is well distributed over the year, has been testified to by all the collectors who have explored the regions of the Andes where they naturally grow. It might be anticipated, therefore, that in Java cinchona would thrive well and especially so as the Dutch are known to be excellent cultivators; and their success has as a fact been great. I have no hesitation in saying that all the species of cinchona are to be found in greater perfection in Java than in Sikkim or the Nilgiris, and (judging from what I saw of their cultivation in that island some years ago) I believe I may also say than in Ceylon.

5. In Sikkim we have, however, the advantage of much cheaper labour than in Java. The expenditure on the Dutch plantations for the year 1877 (the latest for which returns have been published) was fifty-seven thousand guilders (a guilder is of about the same value as a rupee, and in 1876 it was forty-five thousand, the number of plants, including nursery stock, being 2,150,000. In Sikkim, on the other hand, the plantation consisted in 1878-79, of 4,881,055 plants nursery stock being included, and the outlay for the year was Rs. 61,000.

6. The cinchona trees, of which the bark has yielded the Dutch such a high percentage of quinine, have all been raised from a parcel of seed purchased in 1866 by the Dutch Government from an English collector named Ledger after our own India Office had declined to buy them. These seeds were got by Mr. Ledger from a half-caste collector, who would not tell where he collected them, and who was murdered soon after. The exact locality in Bolivia where they were gathered therefore remains unknown. Mr. Ledger's seed produced 6,300 trees which have in late years been largely propagated from. Although these trees differ considerably among themselves in shape and size of leaf, in colour of midribs, nerves, and under surface, and although the bark of individual trees (in so far as it has been analysed) varies as to the amount of quinine contained, the majority agree in being much richer in that alkaloid than any other known variety or species of cinchona. The name ledgeriana was orginally given by the Dutch as a plantation name, to distinguish the produce of Ledger's seed from that of the seed collected by others; but as the points of agreement, both anatomical and chemical, between individual trees so originating is greater than their points of difference, it is quite warrantable to retain the name as that of a very distinct variety of calisaya, if not indeed of a distinct species of cinchona.

7. The 6,300 plants raised from Ledger's seed (which are now thirteen years old) all agree in being rather shabby-looking trees, averaging in height 25 feet, and girthing at 6 feet from the ground twenty-seven (27) inches. They have tall stems and rather small, lax, conical heads, the branches of which are more or less distinctly arranged in tiers. The leaves of the majority are long and narrow, for the most part green, but very often with a tinge of red in the footstalk, midribs, and nerves; while those of a few are of an uniform deep purple colour on their lower surface. The mature leaves of all agree in being quite free from hairs. These trees flower much later in life than the other cinchonas; the flower panicles are small; the flowers which are very sweet-smelling are more or less drooping, of a yellowish-white colour, with a tinge of green in the tube, which is short, wide, and inflated at the base. In the majority of the trees there is a total absence of red in the flower; one, however, of the very richest quinine-yielders has its flowers slightly tinged with pink. The seed-vessels are small, short, and almost globular in shape.

8. The Dutch mode of cultivation is similar to our own. The only method which they adopt, and which we have not hitherto tried, is that of grafting ledgeriana on succirubra stocks, and this plan I shall at once ask Mr. Gammie to try. The Dutch have devised a new way of taking the bark crop which they are very hopeful about. It consists in shaving off the greater part of the bark of a living tree to a height of eight or ten feet from the ground, taking care to leave everywhere a sufficiency to cover the wood. It is found that in Java a tree so treated gradually renews its bark, so that in the course of from twelve to twenty months the renewed bark is as thick as the original. This method is far less likely to injure the health of the trees than Mr. McIvor's plan of stripping and mossing which, after extended trials, has been finally abandoned by the Dutch. The conditions are so different in Sikkim, the lives of individual trees being much less certain than in Java, that I am not sure that the shaving plan can be very advantageously worked in our plantations; but I shall ask Mr. Gammie to give it a trial during the present barking season.

9. I have already stated (paragraph 1) that the trees of calisaya in the Sikkim plantation, present great variety in form of leaf and flower. The barks of all these varieties were submitted to Mr. Wood for report, and his analyses showed that while some of them were very poor in quinine, others contained as much as six and seven per cent. of that alkaloid. The calisaya trees in our plantation were obtained at different times, and from various sources. A few of them were raised from a pinch of Ledger's seed obtained at second hand from the Nilgiris. And I have much satisfaction in informing you that after seeing the Java *ledgeriana*, I have no doubt whatever that our three or four best kinds of calisaya are precisely the same as some of the forms of ledgeriana cultivated by the Dutch. It is true that none of the calisaya barks grown in Sikkim contain so much quinine as the best forms of ledgeriana grown in Java, but this I believe to be an affair of climate and soil. All the Java cinchonas are richer in alkaloid than those of Sikkim, and this will, I believe, always be the case, the physical conditions being so much more favourable in that island.

10. Ever since Mr. Wood's analyses showed the excellence of some of our forms of calisaya, every effort has been made to propagate these artificially, experience having shown that they do not come true to seed. Now that I am satisfied that we have in Sikkim the true Ledger calisaya, I am more strongly than ever of opinion that we should go on increasing the cultivation of it as much as possible. I do not anticipate that we shall be able to grow it quite so cheaply as succirubra, or that we shall be able to produce bark of such high quality as the Dutch. But the object of the Indian Government is not to grow a very fine bark for the European market (which is the object of the Dutch), but from the yield of its plantation to produce a good and cheap cure for fever. And even in Sikkim, where the climate and soil are not so suitable as could be desired, I believe we might grow a bark rich enough in quinine to enable us to turn out pure quinine at probably two or two-and a-half rupees per ounce which is less than the price of the London quinetum (a preparation made in imitation of the Government cinchona febrifuge) and greatly below the market price of quinine.

11. I have no doubt that a more suitable locality for cinchona cultivation than Sikkim could be found further south. The cinchonas in South America are never found further north than 0° nor further south than 2?°. Favourable spots might be discovered in Burmah, perhaps in the Andaman Islands, and possibly in the Khasia hills. Such spots should be searched for. In the meantime the conditions in Sikkim appear to me to be sufficiently favourable to promise a moderate success and to warrant considerable extensions of our plantations of yellow bark there. To carry out these it may be necessary to ask for a slight increase in the annual grant for the present plantation. But as that is now being worked to a considerable profit, I hope, when necessary, an additional grant may be allowed.

12. The Dutch Government has hitherto manufactured neither quinine nor cinchona febrifuge from its bark, but has consigned the annual crop to Amsterdam for sale. Of late a few pounds of febrifuge have been made as an experiment at the Medical Depôt in Batavia,—the process followed being that of Mr. Wood, and the product being undistinguishable from his.

13. I may mention that during my recent tour, I have taken every opportunity of collecting living plants for the Botanical Garden and dried specimens for the Herbarium, and that I have brought safely to Calcutta twenty (20) large cases of the former and three (3) of the latter.

THE JADE OF OUR ARYAN FATHERS.

THERE is a good deal of significance in the discussion which has been caused by the discovery of some jade tools in Swiss lake-dwellings. That these tools should be at once recognized as the property of those well-known wanderers, the Aryan race, and that the Aryan race should be supposed to have carried the tools, as they carried their language from their "cradle in Central Asia" to Switzerland, is a remarkable proof of the alacrity of science. The facts as we gather them from a letter published by Professor Max Müller in the *Times* of last Thursday, and from other letters in the same journal, seem to be much as follows. Jade is a mineral which Europe does not produce, and implements of jade have been found in the lake-dwellings of Switzerland. As the mineral is not a European production, and as no one suspects the Aztecs or New Zealanders of having sold it to the lake-dwellers, its original source must be looked for in Asia. How then does the jade come from Asia to Switzerland? Professor Müller has been told, and the information makes him "feel a little giddy," "that the identical scraper was the property of one of the first discoverers of Europe." This is the singular conclusion to which some scientific person has bounded with alacrity. "It was chiefly in order to remove that feeling of giddiness," writes Professor Müller, "that I wished to call attention to another class of tools equally ancient possibly even more ancient, which were likewise brought into Europe from Asia by our earliest ancestors, and which we use every day without feeling the least surprise." Professor Müller alludes to the "Aryan dialects" and his argument seems to be that people who could bring a language with them from a distant home could also bring a jade scraper. And so no doubt, they could; but there does not seem any necessity for supposing that the Aryans carried jade scrapers with them as well as parts of speech.

The *Times*, in a leading article, is naturally much more sure about the matter than Professor Müller. The mind of Professor Müller is slightly staggered by the idea that the scrapers are heir-looms of our Aryan ancestors; but the *Times* proves it to demonstration:—"By a species of exhaustive process of argument the mind is forced to one particular inference. Britons of Brittany, Celts of Ireland lake-dwellers under the shadow of Mont Blanc, must have conveyed with them their jade ornaments and utensils from the far-away home of themselves and jade in Central Asia, for the simple reason that they could have found the material nowhere in their own country. The reason is very simple indeed rather too simple. Let us suppose that, four thousand years hence, a bit of Derbyshire pottery is found in a grave in Merv. A writer in the *Times* of the period will feel justified in saying that, by a species of exhaustive process of argument, the mind is forced to one particular inference. The people of Merv must have conveyed their crown Derby tea-cup from the far away home of themselves and crown Derby in central England, for the simple reason that they could have found the material for Derby ware nowhere in their own country. Then some sceptic of the future will ask whether the people of Merv might not have got the tea-cup by way of commerce. And that theory is not excluded in the case of the jade tool in the lake-dwelling by the "exhaustive process of argument" which forces the *Times* to the inference that the lake-dwellers brought the implement from Central Asia.

In anything like a scientific argument it would be necessary to know among what other deposits the jade scraper was found. Were there none but stone and bone relics in its neighbourhood, or were there weapons of bronze or of other metals? The Swiss lake dwellings are of very different dates. Settlements like them still exist on the coast of New Guinea. Plenty of them survived in the time of Herodotus who describes them. If a Sheffield knife is found in the lake-dwellings of New Guinea, we do not suppose that even the *Times* will urge that the islanders necessarily carried it to their new country from the ancient home of themselves and whittles in Sheffield. There is a simple explanation, which applies just as well to the jade implements in Switzerland. They reached Europe in the course of trade, just as the earlier bronze implements probably reached the lake-dwellers. There is no tin in Switzerland; bronze is found in many of the lacustrine homes, and bronze cannot exist without tin. Perhaps some enthusiasts will maintain that the tin was brought by a new wave of emigration from the east or west. On the other hand if M. F. Lenormant is justified in saying that lake-dwellings continued to exist in Switzerland long after the foundation of Massilia and other Greek towns on the coast of Southern Gaul, it seems quite as probable that bronze filtered through from them to the lake-dwellers as that Sheffield knives reach New Guinea. In the same way the stone instruments, which are found in great numbers in the Isle of Elba are made of a silex which does not exist in the island. They probably were brought over by mariners to barter for some of the produce of Elba.

The antiquity and activity of commerce are facts which the theorists about the Aryan introduction of jade leave entirely out of sight. Why should jade have been brought into Europe by the first discoverers of Europe, where the prehistoric trade routes are well marked and of unknown antiquity? Jade is precisely one of the curious exotic articles which would be in demand when a simple people came in contact with foreign merchantmen. Even in countries where the mineral is common, even among Aztecs and New Zealanders, it is fashioned into relics and held in a certain religious reverence. It is probably, of all stones, the best substitute for metal, and would be hardly less valued than metal when offered in barter. We believe that the whole theory of the introduction of jade by emigrants from Asia is founded on ignorance or forgetfulness of the existence of primæval overland commerce. Whence came the amber which is rudely worked into the necklaces which we find in the earliest Greek tombs? Were the necklaces brought into the Greek islands by Finnish or Scandinavian emigrants from the Baltic coasts? It is well known on the other hand that the Phœnicians got the amber from dealers at the mouths of the Eridanus or Po, and that these dealers were supplied by natives merchants who crossed Germany by a mysterious route, and who carried back into the North the produce of Greek and Etruscan industries. Another trade route from the Euxine sea along the feet of the Carpathians, across Silesia and Pesan to Pomerania and Jutland is marked by the distribution of ancient Greek coins in the soil much as the road of Hop o' my Thumb was marked by the white stones which he dropped as he went. It was from the trade of this route according to some speculators that bronze weapons reached the lake-dwellers of Switzerland. Meanwhile Phœnician commerce had its stations from the Spanish shores where the savage natives worked mines with hammers of stone to the Red Sea and thence to the Indian Ocean. By the Phœnicians all the produce of different nations was distributed as freely as beads and the muskets called "park-palings" are scattered by our adventurers. There is nothing in a state of low civilization, nothing even in the savage state, to make commerce impossible. Articles of barter (women among others) are safely carried across the continent of Australia, through all the hostile or suspicious tribes, by a sort of commercial natives who have the privileges and immunities of mediæval heralds. In Africa, among races still more hostile, there is a constant ebb and flow of exchanges, and European articles filter into the most remote districts of the interior. Our conclusion is, therefore, that the presence of jade implements in the Swiss lake-dwellings is as easily explained as the presence of English beads in African villages where no Englishman has set foot. In the same way we would propose to account for the recent discovery of an Indian money-cowry in a barrow in Cornwall. The cowry came as the beads came, or as that mysterious object of unknown nature, an ostrich shell set in silver, reached the treasury of an early Scottish king. The worthy monarch's records describe the strange possessions, but cannot account for its existence. It was chiefly valued because it was odd, and we may not irrationally believe that the money-cowry and the jade scrapers were prized by primitive collectors for much the same reason. If the lacustrine owner of the jade scraper did not know how to use it as the *Times* supposes, that is only a stronger proof of the fact that he "picked it up" from a merchant-store as a curiosity. This seem rather more likely than the opposite hypothesis, that the Aryan ancestors of the lake-dweller had vapour baths and stone strigils, and that their degenerate descendant while he kept the strigil, forgot the vapour baths.

Our explanation, we feel, is grossly prosaic. It reduces this wondrous jade to the level of the glass bead of commerce. The belief in the virtues of jade as an amulet is to be explained in the same way as the belief in the virtues of countless other fetish stones is explained. We lose sight of "the tempest-buffeted Aryan recovering from his swoon of bewilderment at the strange land on which his feet at length were resting." We have only to offer the sober picture of a lake-dweller, Aryan or not Aryan, swapping some of his produce for the curious smooth stone of some other capitalist. Of course it is impossible to prove that the Aryan (always more or less in a swoon, poor fellow), did not bring the jade, with his grammar and vocabulary, from no one knows where in Switzerland. But on the whole, the more sober hypothesis seems quite as probable. We may admit with Professor Müller that the jade "originally came from well-defined areas in Asia" but we see no reason at all to suppose that "it was the property of one of the first discoverers of Europe." Thus for the moment we escape the disagreeable "feeling of giddiness" which besets friends of the Aryan theory. That whole theory is based on a hypothesis that foreign materials could only be introduced to Europe by the first discoverers of Europe.—*Saturday Review.*

CONSUMPTION OF TEA AND COFFEE IN THE UNITED STATES.

THE following figures are taken from the *New York Grocer* :—

Quantities and values of imported tea and coffee retained in the United States for consumption, and the estimated consumption per capital of population, during the years 1830, 1840, and from 1850 to 1878 inclusive :—

NOTE.—The consumption of tea and coffee in the United States for each year, from 1830 to 1866 inclusive, is estimated by subtracting the amount exported from the amount imported. For the years 1867 to 1878 inclusive, the amounts of the respective articles entered for consumption at the Custom-houses is taken as the consumption. The population is estimated for years other than the census years 1830, 1840, 1850, 1860, and 1870.

CONSUMPTION OF TEA, COFFEE, COCOA.

THE subjoined table shows the home consumption of coffee cocoa, and tea in the United Kingdom, during each of the past three years :—

		1879.	1878.	1877.
Coffee	... lb.	34,696,256	33,393,243	32,830.224
Cocoa	... „	10,111,526	9,930,162	10,060,687
Tea	... „	160,652,187	157,691,762	151,257,237

PROPORTION PER HEAD OF THE POPULATION.

		1879.	1878.	1877.
Coffee	... lb.	1·01	·98	·98
Cocoa	... „	·29	·29	·30
Tea	... „	4 70	4·66	4·52

Against these figures it is interesting to compare the French home consumption of the same articles, showing the insignificant quantity of tea consumed in France, where, in the small country town, it is sold by chemists as a semi-medicine, or "tisane" for colds, &c., and customers are recommended to take a little rum with the tea.

HOME CONSUMPTION OF COFFEE, COCOA, AND TEA IN FRANCE.

		1879.	1878.	1877.
Coffee	... lb.	125,037,000	119,031,000	105,162,200
Cocoa	... „	21,661,200	21,650,200	20,895,600
Tea	... „	902,000	789,800	805,200

PLANTING IN JOHORE.

THE *Ceylon Observer* says :—

Mr. W. W. Bailey, a Ceylon planter, who left for Johore in in December last, favours us with the following account of his "first impressions."

"I have only been to see two ranges, Gunong Panti and Gunong Pulai. I have been nearly all over Gunong Panti, and the jungle and soil certainly compare favourably with any I have seen in Ceylon ; the jungle is, if anything, larger, and the soil very free, and I am sure will grow coffee well. Most of the available land now being opened is less than 2,000 feet elevation, but at that height here one requires two blankets. I am now living in the rest-house at the foot of this range which joins two other (Muntaha and Blumut) much higher, though they have not yet been surveyed, as most men who have been here think that coffee will do better about the elevation of the plantations now being opened. This rest-house is only 300 feet above sea level, and I never feel it too hot. As I write, 5 o'clock P.M., the thermometer reads 72°, and the other day at No. 2 camp, about 1,600 feet elevation, it was down to 63°, early in the morning. Of course I cannot yet give any opinion about the rainfall ; but from all I hear it is very like Uva. I certainly like this range better than anything I have seen, though Gunong Pulai has the advantage of being all opened up at once and of being four hours' nearer Johore Bahru ; but we are quite as near Singapore (about 50 miles), and a large steamer can come from there up the Johore river, to within five miles of this rest-house, to which point a road is to be cut at once by H. H. the Maharajah (there is only a path at present), who is doing everything in his power for the planters and the opening up of his country. Besides this we are to have the Nuwara Eliya of the Straits on a large flat on the top of the mountain. One great pull we have over Ceylon is that there appears to be little or no wind—so much so that I imagine it will be hard to get a good burn. In the last *Observer* I was very sorry to see a letter about coolies having been crimped from Ceylon for Johore. I do not think the coolies were crimped, nor do I think that any of the late Ceylon men now in Johore would crimp coolies belonging to friends they *ought* to have been sorry to leave, but surely the same friends would not grudge us a few Ramasamies to teach the Heathen Chinee how to plant coffee, if got in a legitimate way. The Malays are first-rate men for feeling and talking, but will not work with the mamoty. They are rather like the Sinhalese in many ways; though I do not think they would be complimented by the comparison.

"If we can once get the Chinese to take to coffee planting, there will be no necessity to get coolies from Ceylon or elsewhere, as there is an unlimited supply of the former in Singapore and thousands of them in Johore ; but most of those in the latter are squatters.

"I can see Mr. Mackenzie's first clearing from where I am writing. The filling of 100 acres will be finished in a few days. By all accounts there are plenty of tigers and other wild animals

knocking about. A rhinoceros came to within a few yards of Mr. Garland's camp a short time ago; but the animal wouldn't wait to be surveyed, so I cannot give you the dimensions. I believe there were no shots fired at it."

From the letter of a Straits official to a relative in Ceylon, we have been permitted to quote as follows:—

"I am told that Mr. Deane has many inquiries regarding land in Perak, and many are looking to this country for facilities to embark in coffee cultivation here. Mr. Deane has had experience, in Ceylon and must known what he is talking about, and doubtless the land here is good. If any one applies to you or mentions the subject to you, you may say that from what you have heard the Government will give every assistance, and that the country is one well worth trying. I wrote you that I was afraid perhaps of the seasons being not sufficiently defined, but I have since been told that in the hill districts this is not the case. Anyhow if a man intends embarking his capital in a new country, he will take all this into proper consideration and satisfy himself that he has all he wants before he begins operations. I am led to send you these lines because I learn that there is suitable land in my district for coffee. I hope there may never be occasion for you to come into the wilderness as a pioneer; my experience of this class of men is that they do the rough-and-tumble work and do not reap the proper results. Nor is the life a taking one. I speak from my own experience, and when I look back on what I had to go through as a pioneer, I should be very sorry to see you in such a fix. Labour will be a difficulty here I am afraid as it will all have to be imported. This will come right in time, but the pioneers will have this to face, and the capitalist who will appear latter on the scene will have his path made easy for him. Still I have no doubt that Perak will be a great country some day. I cannot help thinking that this country has an opening for coffee planters, and that it is really worth while for men to come round and see things for themselves."

INTERESTING NEWS FROM JAVA.

(From the *Straits Times*, 19th Feb.)

NETHERLANDS INDIAN NEWS.

"STEAM PLOUGH.—By the steamer *Hendrik* there has arrived, and been landed at Batavia a steam plough that is to be used on the Chikaudie Udek estate in Bantam which as is known, belongs to Mr. Fraser, and is under the management of Mr. Kimball. The plough is manufactured by the firm of John Flower & Co. at Leeds, and is of 8-horse power nominally but of 20 actually. The said firm has sent a skilled workman along with it who had already introduced steam ploughs in to Cuba and elsewhere. We hope, fervently, and on the strength of satisfactory trials anticipate that steam ploughs may succeed here. At present, especially owing to the scarcity of draught cattle, this machine may be of incalculable service."—*Java Bode*, 20th January.

Should this machine—as we have no doubt it will—give in practice equal satisfaction on the rice fields, agriculture in Java, especially during the present scarcity of draught cattle from disease, will possess a powerful assistant, and may become further developed in future. It is estimated that ploughing a *bouw* of land with this machine may cost 10 guilders, and its enterprising proprietor thinks that the purchase money and expenses together (22,000 guilders) may be covered *in one year* by the work done."—*Java Bode*, 30th January.

From the *Dagblad's* report of the trial the following is taken:—

"In flat country the steam plough spares enormously much labour and time. On land in Bantam where draught cattle are now so scarce the machine will be a deliverance. We understand that already many possessors of rice fields have eagerly accepted the offer to plough their fields at 10 guilders per *douw*, because otherwise they have to pay 25 guilders for the same. The *galangans*, however, after the use of the steam plough, which does not stop on their account, must be repaired again which is no small labour. It deserves to be acknowledged that the result of trial by Mr. Kimball, who along with Mr. Forbes, has taken upon himself the sole agency for Netherlands India of Fowler's steam agricultural machinery, is awaited with great interest. Should it succeed, which is scarcely doubtful, people say that the Government intend to order out several of these machines on their account in order to meet the want of draught cattle. Also on the part of several sugar planters attention is being paid to the machine now here, which may play a great part in the approaching crisis of the transition from the contract system to free sugar culture. During the experimental trip with the steam engine this morning, many gentlemen present from the Kalie Besaar were struck with the idea that it might be an interesting festivity for natives and Europeans, if, on the king's birthday the first steam plough in Java could be set to work on the king's plain. Mr. Kimball, the owner of the machine, answered with great disinterestedness that should the Government intimate to him their desire to borrow the plough from him for that purpose on the said day he would willingly for the benefit of the public defer its departure for his estate until the 19th February."

EXPERIMENTS WITH PHOSPHATIC MANURES.

WE are indebted to Mr. Brown for the following report of interesting experiments conducted by him last season:—Having been much interested in the various experiments carried out under the auspices of the Aberdeen Agricultural Association, as also by a number of private individuals, as to the value of certain manures when applied to our turnip crops, but finding that these experiments had been generally confined to plots, and carried out under circumstances and treatment such as could not be practised in ordinary field culture. I, at the beginning of the present season, determined to try the different phosphates, &c., and gave the same treatment as other manures receive in our usual farm practice. Accordingly, when swede sowing had been begun one afternoon, the manure having already been prepared, it was substituted for our ordinary manure. These experiments have not yet been proved; and mention them because, when they had been completed, I wrote to Mr. Jamieson, the well-known chemist of Aberdeenshire, who very kindly replied, and suggested the following should be tried with yellows:—

1. The ground selected to be as uniform in character and condition as possible.
2. The size of each experimental plot to be one-fourth of an acre, and width of drill 27 inches.
3. The application of a general measure containing all the mineral ingredients of plant food other than those experimented with.
4. A nothing plot.
5. Duplicate of each experiment.

The field chosen by me was one of 30 acres, the soil being a good loam, pretty uniform in character; but to reduce any variation to a minimum, each experiment consisited of four drills 400 yards in length, all of which received a fair and regular dressing of about 12 tons farmyard manure—no difference being made from the other parts of the field. The general manure was not applied, as this field lately received a dressing of lime, which would liberate sufficient potash for the wants of the crop, the magnesia being present in the lime; and our Caithness soils are not considered deficient in salt, owing to our vicinity to the sea.

The nothing plot was omitted, as I considered that just conclusions might be arrived at without one; but find out, when too late, my mistake. The quantities of phosphates applied were regulated so that the same amount of phosphoric acid would be applied in each experiment, and represent a rate of 5 cwt. per acre of bones and ground coprolites, extra weight being allowed for the sulphuric acid in the others, with the exception of the last experiment, with consisted of the same kind of manure as was applied to the other parts of the field. The manures applied were all of the best quality, and show first-rate analyses, which might be here given, but refrain, as I am of Mr. Bowie's opinion, that the plainer and more readable such reports as these are made, the better. I may state, however, that the analyses are at the service of any one who may wish them.

The turnips were topped, tailed, and weighed, when the following were the results:—

Manure		Price per acre.			Weight per acre of crop. Tons.	cwt.	qrs.	lb.
1.	Coprolites	£1	7	6	12	10	1	14
2.	Bone-meal	2	2	4	15	6	3	17
3.	Dissolved bones ...	2	16	0	16	2	1	16
4.	Superphosphates (mineral)	2	2	0	15	1	0	0
5.	Dissolved bones and bone-meal ...	2	9	2	16	8	2	16
6.	Superphosphates and ground coprolites .	1	13	9	16	1	0	0
*7.	Usual manure ...	2	11	0	20	8	1	6

* Equal parts of Peruvian guano, dissolved bones, and bone-meal applied at the rate of 5 cwt. per imperial acre.

REMARKS.

Coprolites.—Came away very irregularly, and made little progress for a long time; but after the middle of September made fair progress.

Bone-meal.—Did not come to hoe regularly, and were in consequence like the preceding, blanky. Were behind during summer; but in autumn made good progress.

Superphosphates.—Came away well, and took the lead all summer; but fell away towards autumn, and did no good after October.

Dissolved bones and bone-meal started well, and came in second until toward the middle of September, when they passed the superphosphates, and kept a good first.

Ground coprolites and superphosphates made good progress, but not equal to the preceding.

The last upon the list was not an experiment, but have given the result so that the produce of the other parts of the field may be compared with the results of the experiments. The crop was twice proved, so as to have reliable results; for this object, the weight given being that of the lowest proof.

CONCLUSIONS.

From the foregoing, coupled with observations made during the season, have been led to arrive at the following conclusi ons :—*1st.* That coprolites require a considerable time before they become available as plant food, and in consequence the crop came away irregularly, which results in a weakly plant. This deficiency of soluble plant food is more easily detected during the earlier stages of the growth of the plant than at any other time. No doubt the absence of heat, and the presence of a superab un dance of moisture, increased this effect. The thought has also struck me, that although coprolites be the tribasic phosphate of lime, may it not have undergone at some time, by the action of heat, a process akin to marble, though in a less degree? We know chalk and marble to be the carbonates of lime, yet the one is less soluble than the other, owing to its crystallization. True it may be urged that there is no intermediate stage; still the chemistry of creation is a most wonderful problem, and more intricate things than this may occur in nature.

Bone-meal became more quickly available, this no doubt owing to the decomposition of its cartilage, by which ammonia was evolved, and the solvent action of the roots of the plants. Notwithstanding, I have come to the conclusion that this manure and the preceding cannot be relied upon to give a regular braird and carry the plant through the vicissitudes of the earlier period of its growth, and must therefore be mixed with a more readily available food.

Dissolved bones and superphosphates both give equally good results as to braird and early progress; but the growth does not continue, or the progress does not go on evenly. This may be, perhaps, caused by the manure being washed out of the soil by the continued rainfall of this most exceptional season. I am aware that Mr. Dyer is of opinion that soluble or monobasic phosphates become tribasic phosphate of lime again when they come into contact with lime. If so, this change must not take place instantaneously, as it must allow a sufficient time to elapse so that the soluble phosphates will reach the subsoil, and are thus out of the reach of the plant, as no other reason can be assigned for the stoppage of growth towards the end of the season. Again, it occurs to me that if such a change takes place at once, how do we not hear more about 'reduced phosphates?' the more especially when much of it has been kept over for a year. It may be said that all the lime has combined with the sulphuric acid and that, it being the stronger acid, it won't give place to the weaker phosphoric. But then we must consider the drying agents employed, which consist of cheaper commodities, *viz.*, chalk, &c., which would present a base ready for combination.

Nos. 5 and 6 compare favourably with each other; and were it not for this most extraordinary year, I am convinced more favourable results would have been arrived at. In fact, these two experiments confirm all that I have previously set down, and have impressed upon me the necessity of applying a quick acting phosphate in combination with the slower coprolites and bone-meal. As it is, one would be inclined to experiment further in this direction.

No. 7 comes out with better results than either of the others, chiefly owing to the manure applied. The application of guano, by its ammonia, gives an early, equal, and strong plant; dissolved bones giving the guano a leg up, and, when these are in measure exhausted, the bone-meal takes up the running. We thus secure an abundant supply of plant food in proper proport on, and in an available form; thereby reducing the liability of its being blighted by inclement weather or destroyed by the depredation of insects or birds.

These conclusions are given with every deference to the opinions of others and are in nowise set down as incontrovertible; but simply thrown out, so that others interested in this subject may give their views upon it.

Since this report was written, I have received from Mr. Jamieson the undernoted comments upon the results of these experiments:—'The possibility of your soil being deficient in potash, magnesia, and sulphuric acid, renders all experiments performed to test the other mineral ingredients of plant life doubtful, and it may be often misleading. Of this tendency almost every agricultural paper affords some evidence. That coprolites will get a serious and unfair check this year I anticipate. What we have found in regard to it is—(1) A soil deficient in phosphate only is rendered fertile by finely ground coprolites. In other words, such a soil would alone give little or no crop, while coprolite would largely increase the crop.

'(2) Its action is decidedly slow, and it should always, therefore, be mixed with a little quick acting phosphate—either superphosphate or steamed bone flour. We illustrate the outcome of our inferences by manuring, according to usual practice, a plot with—

Dung	12 tons.		
Bones	3 cwt.	}	costing 40s.
Dissolved bones	1½ „	}	

'against a plot with—

Dung	12 tons.		
Coprolites	2 cwt.	}	costing 28s.
Steamed bone flour	2 „	}	

'Now it is quite evident that coprolites used alone will have a very unfavourable appearance even in a fairly good year, and that being a slowly acting substance in an abnormal season, such as we have passed through, such a method of testing it will give misleading results to the great mass who will not inquire closely into the matter.'

The preceding remarks led me to test the swede experiments, but before giving results I must explain that, owing to the inconvenient manner our manure merchant has of rendering his accounts, I could not learn the price of ground coprolites and superphosphates, and therefore had to take an approximate value, which turned out to be much lower than the price paid for the manure, thus the experiments, which were intended to be of equal money value have been completely upset. Still, I fancy lessons may be learned from the results, so they are given, as undernoted :—

Manure.	Quantity. cwt. qr. lb.		Price per Acre.	Weight per Acre. tons cwt. qr. lb.
I.				
Guano ...	4 2 0		£2 16	3—18 2 2 0
II.				
Superphosphate ...	12 0 0		2 17	6—16 18 1 0
III.				
Grd. Coprolites ...	15 0 0		4 2	6—14 10 0 0
IV.				
Guano ...	2 1 0	£1 8 2		
Superphosphate ...	6 0 0	1 8 9	2 16	11—17 10 2 0
V.				
Guano ...	2 1 0	1 8 2		
Grd. Coprolites ...	7 2 0	2 1 3	3 9	5—16 8 0 0
VI.				
Grd. Coprolites ...	7 2 0	£2 1 3		
Superphosphate ...	6 0 0	1 8 9	3 9	11—16 6 1 18
VII.				
Guano ...	1 2 0	£0 18 9		
Superphosphate ...	4 0 0	0 19 2		
Grd. Coprolites ...	5 0 0	1 7 6	3 5	5—16 18 2 7
VIII.				
Guano ...	1 2 18	£0 19 7		
Dissolved Bones ...	1 2 18	0 12 10		
Bone-meal ...	1 2 13	0 14 1	2 6	6—18 14 2 10

These results, in a measure, confirm my previous conclusions; and have only to add that I feel quite satisfied that if only half the quantities of coprolites and superphosphates had been applied, equally good results would have been obtained.

Apologizing for occupying so much of your space, and the manner in which the matter has been set down, but time will not permit of its re-arrangement

GEO. BROWN, Jun.

Watten Mains, Caithness, N.B.

A VALUABLE PLANT.

THE sunflower is turned to extraordinary account in Lithuania. The seeds yield at first pressure excellent salad oil, and the residue forms excellent oil cake for cattle, who are also fond of the leaves and stalks chopped up. The flowers a little short of bloom are, when cooked, nearly as good as artichokes, and are in the garden very attractive to bees. The leaf, well dried, is used as tobacco. The seed receptacles are made into blotting paper, and the inner part of the stalk is made into a fine writing paper. The more woody portions of the plant which attains great size, are used for fuel. The best is obtained in the Crimea. As an anti-malarial agent the sunflower is most valuable.—*Field and Farm.*

SALT ON WHEAT.

A CANADA paper says :—"In an interesting series of experiments recently made on the farm of the Royal Agricultural Society of England, the manure value of salt was unmistakably indicated. An acre of wheat dressed with 300 pounds of common salt, yielded thirty-nine bushels of grain, with its proportionate amount of straw, while an adjoining acre left unmanured, produced only twenty-nine bushels per acre, with the straw imperfectly developed. The entire cost of the crop is not stated, but this experiment shows an additional ten bushels resulting from the salt were produced at the cost of thirty cents each. In another case a piece of ground intended for wheat was ploughed the preceding fall and again in May, when it was sowed with salt and afterward ploughed before seeding. On the 1st and 2nd of September wheat was sown at the rate of two bushels to the acre. The crop, when harvested, yielded, according to the estimate of the owner, Mr. John Park, not less than forty bushels to the acre, with a luxurious growth of straw. From these and many similar cases, the inference seems to be that salt is a specific for the wheat crop, imparting solidity to the grain and firmness to the straw. But it must be concluded that equally good results will always follow the application of salt."

THE STRENGTH OF MILK.

HAVING to supply a public institution with milk of a specified strength, according to the lactometer; and if by rich feeding my cows yield milk considerably richer than required by my bargain, would it be right and proper to reduce the milk by adding water? Would this be the same as reducing the quality and increasing the quantity by poorer and more sloppy food?

An answer will oblige.—A. B.—[It would be difficult to guide you without seeing the exact terms of the contract. Such usually binds the seller to 'milk new from the cow and all the cream on,' as well as to supply it with the given proportion. If the latter only applies, then you might remove the extra proportion which you seem to have; but in the spring months you will find that the percentage of cream decreases, and you will most likely be saved the trouble of lowering it to the standard. The application of water would bring you within the lines of the Adulteration Act, unless a special exclusion is part of your contract. Linseed, cotton cake, and bean meal give a high percentage of cream; bran, oats, and Indian meal a low one; but it is a fact that the former also give most milk, and are, for cows in milk, cheaper than the others at the general run of relative market prices. If you give plenty of salt, to induce the cows to drink water largely, and also give all your food in a sloppy state, you will, unless your specified percentage is a very low one, meet the difficulty of your case.—DAIRY CONTRIBUTOR.]—*N. B. Agriculturist.*

SOLUBLE *versus* INSOLUBLE PHOSPHATES.

MR. YOOL, Coulard Bank, Morayshire, sends us the following notes of an experiment carried out by him last season as to the comparative value of soluble and insoluble phosphates:—

The soil on which the experiment was carried out consists of a medium loam, naturally good turnip land. It had been the previous year in oats after two years' grass. The variety of turnips was Fosterton Hybrid, which were sown on 18th June 1879. The experimental plots got farmyard dung at the rate of twenty-two loads per acre, along with the rest of the field. The manures applied per acre consisted of—

Plot 1. 6 cwt. finely ground coprolites.
Plot 2. 6 cwt. superphosphate of lime.
Plot 3. { 3 cwt. superphosphate of lime.
3 cwt. bone meal (finely ground).

Plot 2 and 3 came away more quickly, and all through the season had larger and more growthy-looking tops, and covered the ground better than Plot 1. They were topped and tailed, and the bulbs weighed, about the beginning of January, with the following results:—

		T.	C.	Q.	LBS.
Plot 1.	6 cwt. ground coprolites	15	13	0	0
Plot 2.	6 cwt. superphosphate	18	1	3	5
Plot 3.	3 cwt. superphosphate; 3 cwt. bone meal	19	1	3	2

These results show very decidedly in favour of soluble over insoluble phosphates, in so far at least as mere weight of crop is concerned. To the eye there was no perceptible difference in the quality of the several plots, although, of course, it is quite possible that a chemical examination of the bulbs might have shown that those grown with soluble phosphates contained a greater proportion of water than those grown with insoluble phosphates, as seems to have been the case in some other instances. The bone meal was in a fine state of division, and, besides, had been slightly heated, thus rendering both its phosphates and ammonia more readily available, to the latter of which is probably owing the increase of one ton per acre of turnips over the superphosphates alone.

The manures were all good of their kinds, and I can give the analysis of them to any one interested.—*N. B. Agriculturist.*

RHEA FIBRE.

THE Rhea or China grass trials at Saharanpur closed on the 22nd of September, and fibres have been despatched to England for valuation by competent authorities. The result is not expected before January, when the Government of India will declare who has not the £5,000 and the Rs. 10,000. The future production of the Rhea fibre will be one of the most lucrative speculations that capitalists can enter into. A plant to turn out 400 tons of fibre from 300 acres would not cost over from Rs. 45,000 to 50,000 at a total cost of production not exceeding £10 for cultivation and £10 for conversion into clean fibre worth in England from £45 to £60 per ton. The whole outlay would be returned in one year, as in favourable districts the Rhea will give four crops per annum.

Messrs. Van Maanen & Moorrees, of Salatiga, Java, state that after years of experimenting at heavy expense, they have failed to prepare rameh in the manner desired by the British Indian Government when promising a reward of 50,000 guilders for a method of separating from damp rameh the fibres in a clean and white condition, and free from gummy and woody constituent parts. The result is thus described:—

"Notwithstanding every effort they could not fully attain the object in view. They could, indeed, approach it by stamping and beating for a long time the fibre separated by machinery, but with an eye to the market price too much hand labour was required. To effect this portion of the preparation by machinery a fresh series of experiments would be necessary which the state of their finances did not admit of. Even chemically they could not succeed in removing from the bark the viscid matter, which soon becomes hard, without doing damage to the strength of the fibre."

On the other hand, their experiments have shown that the separation of fibre from dried rameh is easier and more profitable than that from the green rameh plant. The only objections to the dry method are that the resulting fibres are not completely white, and that artificial drying would be required during the greater part of the year, but European manufacturers do not consider the former of much consequence, and the cost of the latter is trifling, because the woody portions of the rameh could be used as fuel. Their own funds being inadequate, Messrs. Van Maanen & Moorrees invite the aid of the mercantile community to enable them to alter their rameh mills for the dry method of preparation. Accompanying the circular are samples of rameh so prepared. These showed conclusively that the dry method is the only method by which a pratical result could be obtained.

THE RYOT'S PLOUGH.

MANY are the ploughs which have been either invented in this country or imported from abroad for the benefit of that conservative individual, the Indian ryot, but he has hitherto taken kindly to none of them. Too great weight for his draught cattle, and too great an outlay to start with have been hitherto insuperable objections in the ryot's eyes, and no doubt he has not been far wrong. So inventors are beginning to see that as the ryot will not take to their ploughs they must adapt their improvement as much as possible to the ryot's ideas of what ought to be. That the plough must be light enough for him to carry over his shoulder to the field, and also short enough to enable him to indulge in this favorite pastime of twisting his bullocks' tails, are essential in his eyes, and in this latter respect especially all foreign-made ploughs are deficient. We have lately, however, seen a plough invented and patented by Mr. G. Sibbald Jones, which comes very near to the ryot's idea, whilst it enables him to drive a much deeper furrow.

The shoe, or sole, or body of the plough is made of wood, having a mortice cut in it, at a suitable angle for the reception of the pole or beam to which the bullocks are yoked, and it is fitted with two wedges (one above and one below the beam) so as to adjust the height of the beam to suit the size of bullocks and fix it in the block or body. A handle of any suitable wood and form is attached to the rear of the plough for the convenience of grinding it when at work. The mould board is made of sheet iron, and is moulded to any pitch that may be required (light soil requiring quite a different pitch to that necessary for clay, &c.,) so as to divide, turn once and aside, the furrow in the act of ploughing. The tip or shoe is of steel (it may be made of wrought iron or chilled cast iron), and can be either riveted or bolted to the mould board with a fish plate joint, or be welded to it made either with a pointed, round or square shape to suit the requirements or tastes of the users. The plough may be yoked in the manner common to the country, *viz.*, fixing the beam to the "Jawat" or yoke. The draught is greatly lessened by the use of the coulter, which is of iron, fixed to the beam.

If the ryot is ever to be persuaded to adopt an improved plough, this, we should say, ought to fetch him.—*The Asian.*

NITRATE OF SODA A CURE FOR WHITE GRUB: "TRY IT."

A PROPRIETOR of plantations in Ceylon, resident in the old country, favours us with the following bit of experience, which he thinks may be of service to planters troubled with grub:—

I had a kitchen garden two acres in extent, and I was told that it was impossible to grow carrots in it, on account of the "wire-worm." I tried to grow them in different parts of it, but failed; as soon as the carrots formed roots, they were perforated and of course died. I tried many remedies, such as quantities of salt, 'hot' lime from the kiln, &c., but all in vain; at last I was compelled to grow my house carrots in the field with the other

roots, such as mangolds, turnips, &c. Some years afterwards I was told that nitrate of soda would banish the wire-worm, I therefore tried it on half an acre, ploughing and harrowing the ground and sowing on it by hand broadcast three-quarters of a cwt. of the nitrate of soda. Three weeks after, I sowed the carrots in drills with manure and I had a splendid crop, *not one of them touched by the wire-worm*. Nitrate of soda is a *good manure* and cost me about 17*s*. per cwt. I believe it may be got cheaper now!

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The Annual General Meeting was held on Thursday, the 26th February 1880. THE HON'BLE LOUIS S. JACKSON, C.I.E., *President, in the Chair.*

THE proceedings of the last (December) Meeting were read and confirmed.

The Report from Council was submitted and adopted. The Report enters first into the internal economy of the Society, shewing that after deducting deaths, resignations, and departures from the country, and allowing for elections during 1879, the total real number on the books is 643, which includes Honorary, Associate, Corresponding, and Life-Members. The Report states that there is not much to notice in respect to the financial position; the expenditure and receipts having been almost the same as in the previous year. "There is, however, one item of Rs. 366 for law charges. Such an item has never previously appeared in the books of the Society. It has occurred in consequence of a complaint brought against a native nurseryman, Boomun Mohun Roy, of Chetla (which is within a short distance of the Society's Garden), in whose possession certain rare plants were discovered which were found to be the property of the Society, and accordingly restored. The Deputy Magistrate who tried the case, however, did not consider it proved that the receiver had purchased with a guilty knowledge, and he was consequently acquitted."

The Report then proceeds as follows:—

The annual exhibition of vegetables, fruits, and flowers, was held in the garden in the early part of the year. It was on a more extended scale than that of 1878, which consisted of flowers only. The attendance was fair—probably about one thousand—both of members and the general public. The expenditure for contingent ordinary items exceeded somewhat the amount received by sale of tickets to non-members. The Judges reported favourably of the show in general.

The usual annual importations of vegetables, flowers, and field seeds from England, America, and Australia, were received and widely distributed. With exception of some of the smaller packets from America, the result seems to have been satisfactory. An assortment of acclimatized flower seeds from the Lucknow Horticultural Garden, of the kinds usually grown in our gardens, was also received. These seeds have been indented for the last three years on the recommendation of a former President. They have generally germinated freely; but a complaint having been recently preferred by a resident member as to their worthlessness, inquiries have been made of a few non-resident members who are known to be good gardeners, and the result has proved most favorable.

The demand by members for plants from the garden has been rather greater than in the previous year. The returns of delivery orders amount to 240, but in addition thereto, about 70 supplementary orders have been issued, which is also greater than heretofore; 8,300 ornamental plants have been distributed to members in part return of their subscription. There has also been a sale to members and the public of 2,000 economic plants and 2,900 fruit grafts, besides many cuttings of plants. Among other general ordinary work there has been an unusually large propagation of plants, in order that the stock for distribution during 1880 may more adequately meet the requirements of members; though several kinds noted in the catalogue have been worn out or entirely lost by drought and other causes. Various large show plants of Araucarias, Crotons, and Palms, which had become too large, for pots, have been placed in the garden grounds in substitution of other more ordinary plants for which the demand is now very limited. The roads throughout a portion of the Garden, the roughness of which has been a subject of complaint, have been improved by the removal of metal which was originally put down of too great a size and in too large quantities. The drainage has also been carefully attended to, whereby a larger quantity of water will flow into the tanks. There is, however, still room for improvement in this respect, so as to obtain the *desideratum*, as abundant a supply of water as possible for the continual requirement of the large and annually increasing stock of pot plants. A consignment of ornamental plants, from Mr. Bull of Chelsea, was received in excellent condition during the rainy season. These will in time constitute a valuable addition to the general stock for distribution to members. There has been a fair demand for economic plants—notably mahogany and coffee—both the Arabian and Liberian varieties of the latter. Attempts to raise the latter by cuttings have been but partially successful, while the seeds take a much longer time to ripen and to germinate than the ordinary kinds. The stock of sugarcanes of better kinds having been exhausted, an application has been made to Mauritius for another supply, as there is a constant demand for them.

The thanks of the Council are due to several contributors of plants and seeds—among them the Queensland Acclimatisation Society, Mauritius Botanic Garden, Calcutta Botanic Garden, Baron Ferdinand von Mueller, Rajah Suttyanund Ghosal, Bahadoor, V.P., Messrs. C. K. Hudson, T. M. Francis, and E. H. Man. The latter gentleman has most obligingly sent ten consignments of plants and seeds from the Andamans and Nicobars, of which the palms are especially acceptable.

Applications for seeds of economic plants have continued throughout the year, especially for tobacco, Carolina paddy, flax, maize, cereals, mahogany, Guinea, and other fodder grasses; also for Pithecolobium Saman and Euch'æna luxurians. For the latter useful grass the demand has been very great, and has been fully met in the shape of seeds and plants.

It was stated in the last Report that the Society had been reluctantly compelled to abandon altogether, for want of support on the part of those most interested, a scheme towards a full inquiry for the investigation of various blights affecting the tea plant. The several applications made to the Society during the past year, for information in connection with insect, pests of various kinds, and the serious ravages, greater than ever, committed during 1879, and consequent decrease of produce, on gardens both in Assam and Cachar shew still more forcibly the necessity for close and careful investigation. The question of a proposed remedy for the ravages of the coffee blight (Hemileia vastatrix) as probably applicable to tea blights, was moved at a recent monthly meeting; but it seems doubtful, on further investigation and trials, whether the external application of sulphur "is likely to be effective in curing, or in even mitigating to any very satisfactory extent the ravages of the [coffee] leaf disease."

From the monthly proceedings of the past year it will be seen that among other matters, reports have been furnished on sundry specimens of field produce including tobacco, cotton, and fibres of sorts; further that notices have been introduced respecting the development of the wild silk industry of India and Indian wheats, subjects which in past years engaged considerably the attention of the Society. It is satisfactory to find that the former is now likely to be fully utilized in a variety of ways, and that the export trade of the latter is annually becoming more important.

Only one number of the journal was published during the year, Vol. VI., Part 1. Part 2 is now in the press, and will be distributed to members in the early part of 1880.

The election of officers and Council was next entered on, with the following result:—

President.—The Hon'ble Louis S. Jackson, C.I.E.

Vice-Presidents.—Mr. W. H. Cogswell, Mr. W. Stalkartt, Rajah Suttyanund Ghosal, Bahadoor, and Baboo Peary Chand Mittra.

Secretary.—Mr. A. H. Blechynden.

Council.—Mr. J. W. O'Keefe, Mr. R. Blechynden, Dr. S. Lynch, Mr. W. Waterfield, Baboo Protapa Chunder Ghose, Mr. J. E. MacLachlan, Dr. Geo. King, Dr. J. B. Barry, Mr. S. H. Robinson, Mr. H. J. Leitch, Mr. John Martin, and Mr. G. L. Kemp.

Mr. Kemp's name has been added to the Garden Committee.

The following gentlemen were elected members:—

Dr. W. H. Gregg, Sheik Atta Hosen, Messrs. James F. Smart and G. E. Keith.

The names of the following gentlemen were submitted for membership:—

His Highness the Maharajah of Burdwan,—proposed by the President seconded by Baboo P. C. Mittra.

Dr. R. F. Swaine, Civil Surgeon, Ranchi,—proposed by Captain L. J. H. Grey, seconded by the Secretary.

H. Pratt, Esq., Manager Messrs. Osler & Co.,—proposed by the Secretary, seconded by Mr. R. B. West.

L. G. Middleton, Esq., Proprietor, Mahelon Tea Estate, Ranchi,—proposed by Capt. Grey, seconded by the Secretary.

James Hutchinson, Esq., M.A., Old Saloua, Kabaom, Assam,—proposed by Mr. G. L. Kemp, seconded by Mr. H. J. Leitch.

Edwin Kock, Esq., Advocate, Supreme Court, Singapore,—proposed by the Secretary, seconded by Mr. W. Stalkartt.

Harry Morison, Esq., Managing Proprietor, Koleapanie Tea Estate, Jorehaut,—proposed by the Secretary, seconded by Mr. R. Blechynden.

PRESENTATIONS.

The following presentations were announced:—

1. Further supplies of seeds and plants from the Nicobars. From E. H. Man, Esq.

2. A Geranium plant from Dundee. From A. J. Millner, Esq.

3. Spanish Melon seed of a superior kind. From J. D. Ward, Esq.

4. A bag of imported mahogany seed. From Dr. Thwaites, Director, Royal Botanic Garden, Ceylon.

5. Three kinds of Cupressus seeds. From J. F. Duthie, Esq., Superintendent, Botanical Garden, Saharunpore.

6. A few seeds from the "indigenous tea plant," referred to in a previous communication. From G. F. Pinny, Esq., Rungajaun, Assam. These have been recognized by Dr. King, as the produce of *Camellia drupifera*.

7. Six Brinjalls or Egg plants (*Solanum melongena*) of 3 kinds; 2 of each, of an unusually large size. From H. W. Stevens, Esq.

Mr. Stevens states that these are the produce of acclimatised English seed, imported three years ago, and the largest specimens selected for seed. Less than one acre of ground has yielded 366 maunds of this vegetable at Durbhunga, Tirhoot.

8. A basket of Buist's early acme Tomatos raised from seed distributed by the Society. From Mr. R. B. West.

These have been grown by the side of Vick's Criterion and Carter's Greengage, and have been found good in every respect.

9. A small plant, in flower, of "Geranium, Cannell's New Life." From Mr. West.

Mr. West exhibits this not so much for the striking novelty of its flower, as for the fact that this plant, with eleven other Geraniums, arrived here only six weeks since from England by overland parcel post, ten out of which are now alive and growing well. They were despatched at end of November, when the plants were nearly in a dormant state, all the stems were carefully bound with moss, and the plants packed with the same."

Hyacinths.—Mr. John Martin exhibited two plants in flower—blue and white—"Grand Lilas" and "Mont Blanc."

Mr. F. A. Lazarus also shewed two in flower—'Grand Lilas" and "Charles Dickens ;" and one came from the Society's Garden (red flower) named "Lord Derby."

The Rajah Suttyanund Ghosal placed on the table seeds of a creeper known as "Shah Possum." Baboo Peary Chand Mittra observed that this seed in a powdered state is said to have cured leprosy. He had ascertained this from Pundit Eshwan Chunder Vidyasagur, and Professor Rajkrishna Banerjee, who had, moreover, told him that the number of applications for this seed was so great that they could not meet the demand. These gentlemen had promised him a statement which when received, would be submitted to the Society.

HORTI-FLORICULTURAL EXHIBITIONS.

The following reports of the Judges on the show of vegetable and fruits held in the Town Hall on the 29th January, and of Flowers held in the Society's Garden on the 16th February, were submitted :—

HORTICULTURAL.—*Judges* :—Messrs. W. H. Cogswell, W. Stalkartt, S. H. Robinson, and Baboo Peary Chand Mittra.

The show was perhaps the largest, or one of the largest held during the last 40 years, or since such exhibitions were commenced. About 80 market gardeners besides a few private gardeners were in attendance ; a few bringing as many as 20 baskets, others 16, and others 12, some only 1 or 2; but the average was about 10 equal to 800 baskets in all, containing 24 or 25 kinds of European vegetables, a few native vegetables and a fair collection of fruits. The tables in four lines arranged for their reception, two baskets in each row, occupied some 600 feet and extended nearly the whole length of the hall. Notwithstanding this accommodation, it was found necessary to place many baskets—about 200 feet in length—on the floor. Had so large a display been anticipated, additional tables would have been provided.

Among the European vegetables—Cauliflowers, Cabbages, Knole-Kole, Turnips, Beet, Carrots, and Onions, were most largely displayed, and among them were some very well grown specimens. The Celery was fair, and Peas also. There were several baskets of Artichokes and Asparagus, though too early in the season for a fair display. Among the native vegetables, there were several baskets of well grown specimens of Beans, Chillies, pot herbs, and Indian Corn. In the Fruit Department—Baels, Limes, Citrons, Sapotas, and long plums were conspicuous ; there were also Pummelows, Guavas, Pineapples, and Custard Apples, though out of season.

A list of the prizes, amounting to Rs. 281, is hereto annexed.

The thanks of the Society are due to the Chairman of the Municipility for the free use of the basement story of the Town Hall and tables belonging thereto. Also to the Manager, Great Eastern Hotel Co., for the free use of tables.

FLORICULTURAL.—*Judges* :—Dr. G. King, Messrs. W. Waterfield, G. L. Kemp, and W. Pigott.

The collection of plants rather exceeded that at last year's show. The competition was about the same. The produce of some twenty gardens was placed under the tents. The display of handsome foliage plants, such as Dracænas, Begonias, Palms, Crotons, &c., was tolerably good. The assortment of Roses in pots was limited, it being rather late in the season ; but the boxes of cut specimens were excellent, especially those submitted by Colonel May, from Chupra, and the Belvedere Garden. The collection of annuals was considerably in excess of last year (when the show was held a fort-night earlier) consisting, among others, of Asters, Pinks, Pansies, Phloxes, Snapdragon, Tropœalum, Portulacas, and Petunias. The Asters, Pinks, and Heartsease were especially good Verbenas, also were well represented.

Among novelties were plants of Azaleas, Fuchsias, Eucalyptus citriodora, and a Tree Fern. There were more specimens of Camellias than heretofore. For orchids in flower the season was too early ; but there were a few good specimens from Baboo Prosonno Coomar Bannerjee's garden, and a fine example of Vanda gigantea from the garden of Rajah Suttyanund Ghosal, Bahadoor.

The Royal Botanic Garden contributed some fine grown plants to add to the interest of the show. These were not in competition for prizes. Among these sent from the Botanical Garden may be mentioned :—Phalaenopsis amabilis, Saccolabium Harrisonianum, Cypripedium venustum ; several new introductions from Java, Mauritius, and elsewhere, such as Pinanga maculata Areca cridita a new variegated Tradescantia a number of Cacti, not previously exhibited in Calcutta, and some pretty new ferns from South America.

The Belvedere Garden collections were the largest, and many prizes were awarded for them. The cut specimens of Roses, as already remarked, were excellent. Crotons, Dracænas, Palms, and Begonias were most prominent ; also a large collection of annuals.

The Eden Garden likewise contributed largely and gained several prizes. They shewed especially in Crotons, Palms, Dracænas, Begonias, and annuals ; also Cactus plants.

The President's prizes, for rare and well grown plants not included in the general list, were completed for by Mr. E. G. Keith for a Tree Fern, for Fuchsias and Eucalyptus citriodora ; by Mr. H. C. Rostan, for Azaleas ; by Baboo Prosonno Coomar Bannerjee, for a collection of Orchids ; by Rajah Sutyanund Ghosal, for an excellent example of Vanda gigantea, and by Mr. D. Low, for a collection of 12 Ferns.

Mr. Low gained the first prize for the best collection (12) Crotons, and Moulvee Ahmed for the second best. Baboo S. P. Chatterjee for the best collection of Crotons of recent introduction, and the Belvedere Garden for the second best. Mr. Low also exhibited a glazed stand containing a fine example of Adiantum Farleyense, and a stand covered with Adiantum, Capellus, Veneris, and other Ferns plants, 46 in all, to which prizes were awarded.

From Mr. Pigott's garden came seven new varieties of Coleus, fine specimens of Dracæna Gouldieana, Davidsonia pruriens and Macrozamia plumosa, a new Cycadaceous plant. These gained the first prize for new and rare plants.

Mr. R. B. West gained the first prize for the best collection of Dracænas of recent introduction.

There was a large attendance of visitors, probably one thousand, including children. The show was opened at 4, and lasted till dusk.

The best thanks of the Society are due to Colonel Rogers, V.C., and Officers of H. M.'s 90th Regiment, for the attendance of their fine band.

The sum of Rs. 309 was awarded in prizes, of which a list in detail is annexed.

The Judges would suggest that a clause be introduced in the conditions, rendering it imperative on exhibitors to allow their plants to be properly arranged by the Society's Gardener, that is to say, each kind to be separately staged together, so as in future to save the Judges unnecessary trouble in awarding prizes.

FIBRE FROM KUMAON.

The Secretary drew the attention of members to a communication in the proceedings of the last meeting from Mr. J. G. Bellairs of Chowkooree Tea Factory, Almora, Kumaon, respecting sample of a fibre procured from plants growing on his estate, and of cloth made therefrom ; also to the report of the Fibre Committee thereon. He had since received a specimen of the plant from Mr. Bellairs, which Dr. King has recognized as *Maoutia puza, Wedd-Bœhmeria frutescens*, Ham. and Don. The Secretary further called attention to the fact that so long ago as 1847, Dr. A. Campbell, then Superintendent of Darjeeling, brought this fibre to the notice of the Society and gave a short description of it, its habit at, when used, how prepared, &c. A favourable report on the fibre was made by the Committee who valued it at Rs. 12 per maund, and were of opinion that "if properly prepared and dressed, the *Poaah* is capable of being converted into fibers much finer than either sale cloth or sewing twine." (All these particulars will be found in the journal Vol. VI., old series).

COMMUNICATION ON VARIOUS SUBJECTS.

1. From Capt. J. F. Pogson, Koteghur, on the subject of *Sorguhm saccharatum*, as a new food grain for the hill people.

2. From H. James Rainy, Esq, Khoolna,—a paper on the Field Rat of Bengal.

3. From T. M. Francis, Esq., particulars of trials made of upside-down cuttings of plants.

4. From Capt. Pogson, details regarding the propagation of the Singhara nut in reply to inquiries by Mr. L. Bernays of Queensland. The above four papers were transferred for publication in the journal.

5. From E. Buck, Esq, on the subject of certain of the S. African *Euphorbiaceœ*, whose juice is stated to be a preservative for iron. (*See* Col. Lee's letter read at last meeting.)

The Secretary mentioned he had, previously to the receipt of Mr. Buck's letter, addressed the Superintendent of the Cape of Good Hope, Botanic Garden, on the subject.

6. From the same, in respect to seed of the Argan tree of Morocco. Seed daily expected from the Society's seedsmen at Erfurt, Messrs. Haage and Schmidt.

7. From Messrs. Williamson Magor & Co, in respect to a certain communication from Mr. Grote, regarding tea pests on the Munguldye Tea Company's Estate, to which the manager's particular attention is requested.

In connection with the above, the Secretary submitted further correspondence on the coffee leaf disease, with which he had been favoured by Dr. Thwaites, the Director, Royal Botanic Garden, Ceylon, which shows a great difference of opinion in respect to the proposed sulphur remedy.

8. From the Hon'ble H. T. Prinsep, Chairman, Economic Museum returning thanks for the specimen of first manufacture of Andaman raised tea.

9. From the Director, Smithsonian Institution, Washington, returning thanks for copies of this Society's publications.

MINERALOGY.

THE very considerable speculative success which has attended the issue of the South Indian Gold Company, is having its natural effect in bringing to market other projects of a similar nature, and the last mail brought the prospectus of the South-East Wynaad Estates and Gold Mining Company, the capital being £100,000, in shares of £2 each, of which 12,500 shares are taken by the vendor, and the remainder are offered to the public. The Company is formed to acquire, cultivate, and develop several estates in the south-east Wynaad, and to extract the gold from the numerous quartz reefs which traverse them. Included in the various properties is Needle Rock, consisting of 771 acres, of which 147 acres are planted with coffee and 20,000 cinchona plants. Two valuable gold quartz reefs run quite through this property, and are named Buckingham and Chandos, after his Grace the Governor of Madras, who visited and inspected the reefs, when gold was washed in his presence. The other properties, which are of a like character, extend over 700 acres. Mr. Brough Smyth's unqualified opinion of the gold-bearing value of these properties is substantiated by documents bearing his signature, and his report is not only corroborated by the many eminent mining engineers, who have visited the district, but by assays made by London expert. Four boxes of stone by Mr. C. R. Dawson, from the estates now offered, yielded an average of 2,285 oz. per ton ; and, in addition to this, one of the samples showed 3,947 oz. of silver to the ton of quartz. This result was obtained from surface stone only, selected by planters who knew nothing of mining or the selection of stone, and no gold was visible in the specimens which were the subject of those assays.

MR. EASTWICK has an idea that the "Havilah where there is gold," to which reference is made in Genesis, is synonymous with Devalah in the Wynaad, where gold certainly exists. There are already fourteen mines at or near the Devalah, and there can be no reasonable doubt that large quantities of gold were in olden times obtained from that locality. In fact before the discovery of the gold fields in Australia and California, India would seem to have been the country whence the world drew the bulk of its gold supply. So recent as the eleventh century if the inscriptions on the Tanjore temple which have been deciphered by Dr. Burnell may be relied upon, "gold was the most common precious metal in India, and stupendous quantities of it are mentioned hear;" whereas silver was hardly known in India until the 16th century when the Portuguese brought it to India with them. Parts of the Wynaad and Mysore are honeycombed with ancient mines; and the contention is that the miners with their rude appliances only tapped the shell of the Indian *El Dorado*. Those ancient miners were "in the habit of making their shaft in a triangular form, they lighted fires in two of them to calcine and break up the rocks, and by the third which also gave the draught of air necessary for the fires, they ascended until the shafts in which the fires were had cooled." Nothing could well be more primitive. But now quartz-crushing machines of the newest types, and skilled engineers and miners are hurrying to India to dive far deeper into the bowels of the earth than their predecessors in ancient times ever dreamt of men penetrating; and should they come up smiling with quartz much impregnated with gold in their hands, we may have to record a great change for the better in the condition of this Presidency and Mysore in general, and of the coffee lands of Wynaad in particular.

GOLD PROSPECTING IN WYNAAD.

MR. J. W. MINCHIN, Secretary, Wynaad Prospecting Company (Limited), has requested that a mining lease may be granted to the Wynaad Prospecting Company (Limited), for 50 acres of land within the boundaries originally granted for prospecting operations. "The result of our workings," writes Mr. Minchin, "has enabled us to make arrangements for the further prosecution of mining work which will now be carried on with vigour." He further requests that a grant for prospecting operations may be given to the Wynaad Prospecting Company (Limited), on another portion of 100 acres within the boundaries originally applied for, to be followed hereafter by a mining lease for such portion as may be permitted under the rules about to be framed. Both plots are in the Cherankod Amshon, and adjacent to one another between Devala and Cherambadi. The Government in their order state:—"The Commissioner will request Mr. Minchin to demarcate clearly the two blocks of land he applies for, and to submit sketch-plans of them, showing approximately their position and boundaries. Meanwhile Mr. Minchin's application will be registered, and on the sketch being received, the blocks will be surveyed at Mr. Minchin's expense. Possession of the block of 100 acres may then be made over to him for twelve months for *prospecting* purposes, on the distinct understanding that unless within that period he selects a block of land within the limits of the 100 acres, not exceeding 30 acres in extent, and applies for a *mining* lease for it, the right of prospecting shall lapse, and the possession of the land shall be given up to Government. As regards the block of 50 acres, for which a *mining* lease is now asked for, Mr. Minchin should be informed that no gold-mining lease for an area, in excess of 30 acres is likely to be granted, nor can any lease be granted at all till the terms on which they are to be granted have been settled by the Secretary of State."

GARDEN.

MANGO GRAFTING.

THE following is an account of Mango Grafting, practised with some success as regards numbers of grafts and cheapness at Allahabad, by the Superintendent of the Government Botanical Gardens:—

"*Process of Grafting Mangoes on the Tree.*—The process by which this is accomplished is very simple. In the first place the seedling with seed attached thereto, when it is about 6 or 8 inches high and three weeks old, is carefully lifted with a small ball of earth. The roots, with the earth intact, are then wrapped up in a little grass, and the young seedling plant tied to the tender branch of the tree required to be grafted from, care being taken that the young seedling tree and the branch to be grafted should lie pointing in the same direction, and be of the same age, *i.e.*, both seedling and graft should be of that year's growth. When grafted the joint should be covered with grafting clay to exclude the air.

"2. The roots of the seedlings, suspended as above described, when grafted must be kept moist by watering, either by hand or with a garden syringe in case there be not sufficient rain.

"3. The process of grafting should be commenced in the beginning of the rainy season, as soon as the young mango seedlings are procurable. The plant should be ready for cutting, *i.e.*, the graft should have taken well within a month; but I have succeeded in cutting them so soon as thirteen days after grafting, and the plants so removed are now in good growth in the nursery. In fact, plants thus grafted in this season are now growing strongly and ready for sale. The plants grafted in this way on young wood, where the junction is so complete, will, in all probability, be much stronger than those grafted on two or three years' old plants where the wood being hard between the grafts, such a complete union is impossible, from which cause a great number of plants die or are broken down by the wind.

"4. The following is the actual cost incurred in raising 2,000 grafted mango trees by the above method:—

	Rs.	A.	P.
To digging bed and growing seed	1	0	0
" lifting and tying up plants for grafting ...	4	4	0
" grafting 2,200 plants	5	0	0
" bhisti watering, one month	4	8	0
" cutting and planting the young grafted trees in bed	2	8	0
" twine for tying plants to trees	2	2	0
Total ... Rs.	19	6	0

Total say Rs. 20, equal to less than 2 pie per plant; add watering in the nursery for one year, Rs. 10; the plants when ready for sale would thus cost about 3 pie per plant. Plants raised at such a trifling cost, and in such numbers, and which promise to be so hardy, should soon take the place of the common seedling mango trees on roadsides, canal banks, topes, &c."—*Planters' Gazette.*

ON THE FUCHSIA.

THE present being a good time for starting the fuchsia into growth either for the purpose of propagation or for shaking out and repotting specimen plants, a few remarks on the general management and culture of this popular greenhouse plant will now be seasonable. The fuchsia delights in very liberal culture, not only as regards the pabulum supplied to its roots, but also in regard to the management of the atmosphere. Supposing the cultivator to be in possession of old flowering plants—that is, plants of last year's propagation or older, which have been kept during the winter, it may be under the greenhouse stage, or in any other cool place, stinted for water, but not kept dust dry—let them be brought out and placed in a temperature of 55 degs. at night, with a rise of 10 degs. during the day, giving them a thorough soaking of water to moisten the ball through and through. Thus treated, they will soon break their buds and rapidly push shoots. If it is only intended that these old plants should furnish as many cuttings as may be required for stock and be then destroyed, they should not be shaken out, but be encouraged with liquid manure to make healthy, vigorous growth briskly. On the other hand, if the old plants are to be grown again into flowering specimens, let them be shaken out and repotted as soon as the shoots have advanced to about an inch in length. This shaking out should be done very thoroughly—so thoroughly that the plants may be potted in the same or smaller sized pots, in a compost almost wholly new, for very little of the old soil should be allowed to remain attached to the roots. The compost should be concentratedly rich, the bulk being formed of rich loam roughly broken up, so as not to break up the fibre too fine. To two parts of this loam add one part old cow manure, well matured and dried, so that it will rub through the fingers without clogging them, and one part rough partially decomposed leaf mould, from which all sticks and woody fruits, such as beech-nuts, have been carefully picked in the process of turning over. Add a spadeful of roughish bone-meal and two spadesful of sharp sand to every bushel of this compost and turn and mix altogether in such a way as to incorporate them thoroughly, when it will be ready for use. Use clean pots only in repotting. If they are not new, let them at least be washed clean.

Drain them well. This is an important point, for although the fuchsia requires very liberal allowances of water during the growing season, it is very impatient of stagnation. After being repotted, the plants will be returned to their place. A moist atmosphere must be maintained for them, and for a few days, till they have begun to strike root into the new soil, let them be shaded from bright sunlight. They must be sparingly watered till they are observed to be making some progress in growth; but they may be moistened twice or thrice daily with the syringe, to keep the foliage plump and healthy. As they advance in growth, the supply of water must be increased; and when they have filled the pots with roots, they should be shifted into others a size or two sizes larger, using the same compost as that detailed above. When the plants have filled these second pots with roots, it must be considered whether they will attain to the desired dimensions in such pots. And here it must be observed, that although the fuchsia will take almost any practicable allowance of pot room, it may be grown to almost any size in comparatively small pots. If the compost is as rich as it ought to be, and yet porous and freely permeable to water, gigantic specimens may be grown to perfection in small pots. It is no unusual thing to see plants seven or more

feet high, with proportionate width, perfect pyramids, in fact laden with richest profusion of flowers, yet growing in ten or twelve inch pots. Such perfection in such small pots can only be attained by means of patient care and much judicious and skilful application of practical experience in the matter of watering. Such bulk of foliage and flowers cannot be developed but by means of frequent and skilfully adapted applications of stimulating liquids to the soil. But for the inexperienced amateur, or for such cultivators as cannot give the requisite time and attention to plants of large growth like these, it is better that they should take the more safe method of allowing plenty of pot room for their plants, taking especial care that the pots are well drained.

Cuttings of the fuchsia are, as even the most inexperienced window-gardener knows well, easily rooted with very ordinary facilities for propagation. Cuttings are rooted in many a cottage window throughout the land, with no better facilities than the surface of the parent pot; a slip being taken from the parent plant, in many a case, and having a cracked or sound tumbler, as the case may be, inverted over it, and in the crude ill-conditioned soil in which the parent plant grows, quickly roots and establishes itself. And these simple means meet all the requirements of the window-gardener, supplying sufficient for his own stock, and to gratify his neighbourly and generous instincts of presenting to, or exchanging with, his friends. But these are not the kind of the conditions we have in view, although we do not despise them, but rather rejoice that the humble craft and patient care of the cottage window-gardener throughout the land can produce such excellent results. But for the majority of the readers of the *Agriculturist*, something superior will be rightly considered within their reach. A one-light frame, at least, that can be converted into a hot-bed at will, may be looked upon as perfectly practicable and within reach. With a well managed hot-bed frame, excellent work may be done. In fact, if well attended to, there is nothing better in the whole range of modern appliances for propagating purposes. The cuttings should be taken while they are quite young and growthy. To leave them till they become partially matured is certain to result in failure. Starting with a fresh young cutting, the tissues of which are soft and prone to grow, there is not the least likelihood of failure if checks be avoided; and this is the most important point to bear in mind in fuchsia growing. Once the growth of the plant is checked, little more good may be done during the current season with it. We shall leave the treatment of the cuttings and subsequent treatment of the young plants as subjects for another paper.—*N. B. Agriculturist.*

TEA.

We are glad to see that the Kumaon correspondent of the Agra paper says "a number of contracts are already being entered into for green tea of next season, for export to Bokhara and Northern Afghanistan." This is the right sort of aggression on Central Asia; and if half as much pains had been taken by the Government of India in that way as in the export of bullets and shells we need have had no Afghan war. So much for the green tea. As to black tea, which Britons affect, we learn from one of the principal proprietors of the Kangra Valley estates that several considerable orders have already been given in London for teas from those northern gardens in anticipation of the crop that will not be ready for two months to come.

We hear that the Government have decided on sending an expert to the tea districts to study the various blights, and we think that the selection of their agent could not well have been better. At the same time we think that much good would have resulted had this gentleman been accompanied by a practical tea-planter, as we understand he is ignorant of the habits of the plant, his experience, which is of the best, having been altogether in the insect line. As we understand he proceeds shortly on his mission, it may not be too late yet to send a companion with him, who would always be at hand to keep him right on the more purely agricultural part of the subject. We trust that he will not be hurried, and that he will be allowed to see the plant in all seasons, that his examination will not be a superficial one, and that no preconceived theories will be attempted to be forced upon him, as the best intentioned efforts may be entirely nullified by endeavouring to compel observations to tally with a preconceived theory instead of working out a theory from those observations.

In addition to the movement at present on foot to send a Commissioner to the Melbourne Exhibition to represent the tea interest in India, we observe that private efforts are being made, having the extension of business as their main object. Three of the largest tea agencies in Calcutta have we observe, appointed an agent in Sydney, who seems to be pushing their interests in a manner calculated to forward the object in view. This agent is busy making the tea up into small attractive packets of half and whole pounds each, and these he is selling, and in some cases distributing *gratis*. A large number of pamphlets have been printed for gratuitous distribution, and these efforts cannot fail to have a good effect. The pamphlet consists of a short history of the plant, and of the modes of growth and manufacture of Indian, as compared with China teas. It has evidently been got up rather hurriedly, and a second edition may correct a few slips made by the writer, which, although of no material importance, had better be put right, as absolute correctness would leave no room for fault-finding. We are sorry that the agent recommends a "blend" for Australia. Such a mode of proceeding will infallibly hinder the growth of a taste for Indian teas. Buyers using a "blend" will never know to which section of the blend they are indebted for any particular flavour. Let the Indian tea be invariably sold pure, and the consumer can, if so disposed, easily blend it with any proportion of China tea he desires. If, on the other hand, he proposes a "blend" of the different classes of Indian teas, we are at one with him, although in passing, we may be permitted to point out here, that this craving for a blend of Indian teas, which is growing at home and elsewhere, is simply a protest against the system now in vogue on many gardens, of dividing and sub-dividing the crop into innumerable classes, which had better be all left together.

We have on more than one occasion spoken of the necessity for great efforts in the direction of making Indian tea by some cheaper method. It seems evident that the present low prices at home are not, as has been supposed, abnormal prices, but the ordinary prices which the very materially increased production has brought about. So long as this increase was followed by a corresponding increase in consumption, prices did not suffer, but now that it is evident that consumption has failed to keep pace with production, we must meet the depreciation in price, either by reducing our exports to the United Kingdom, or by so reducing our producing expenses that we shall be able to accept, without loss, the very much lower rates now obtaining for our teas. Regarding the former alternative, there seem to be two important markets which we have neglected, Australia and America; and it is only by finding new markets that we can hope to reduce our exports to Great Britain. A movement has been all but consummated here, having for its object the opening up of Australia as a market for our teas. The present consumption in the Australian colonies is about 16 million pounds, and the half of this secured to India would relieve the London market, materially reduce stocks, and tend largely towards an increase in value. This consumption in a few years will rise to 20 million pounds, or half the production of India, and as all this large supply is at present drawn from China, there is no reason why our teas should not try to compete with China teas. Now we come to the United States of America which derive nearly all their supplies from Japan. Their consumption of Japanese teas is at present 32 millions, and of Indian teas almost *nil*. There seems no reason why the Americans should not be induced to try our growths. There remains the cheapening of production. As we have repeatedly said, no tea should cost more than eight annas per pound, and whether the normal selling price of tea stands as at present, or rises to the rate at which it stood a few years ago, shareholders should all the same insist on having their tea made at eight annas per pound. In fixing this rate we have not forgotten the labour difficulty in Assam, but have made allowance for it. In districts where this difficulty does not exist, the tea should not cost so much as eight annas per pound. In the Upper Provinces, for instance, where labour is plentiful and cheap, tea need not cost over seven annas per pound, laid down in Calcutta. A letter in the *Statesman* of the 19th, speaks of a Company paying its Calcutta Agents an agency fee equal to 12 per cent. on the gross proceeds of last season. It is too much, in these days, to expect that a tea business could stand such a charge. It behoves shareholders to take a warmer interest than they have hitherto done in their own concerns, and they will doubtless find that there are many items of expenditure on which the pruning knife might be used with advantage. While we sympathise with "An Unfortunate Scrip-holder," who signs the letter referred to, we cannot help remarking that the cause of those excessive charges is due very largely to the apathy shewn by scrip-holders in general.

BAD TEA.

"A GREAT many letters," says the *Times*, "have lately reached us drawing attention to the present demoralised state of the tea market. It would appear that the rise which took place in the latter part of last year in the price of common teas has caused the shipment from China of large quantities, some say as much as 100,000,000lb. of rubbish utterly unfit for human food. Dressed up and passed as sound tea, this rubbish is now finding its way into consumption here without apparently any interference on the part of the Custom-house authorities. The abuse ought to be looked into before further mischief is done."

Messrs. William Stewart & Co., of Great Tower-street, call attention to this matter as follows. They say:—"A rise of 4*d.* per pound on good common Congou took place on the London tea market in October last, the news of which was telegraphed to China, with the result that nearly 10 million pounds (not 100 million, as stated in the *Times* of 31st ultimo) of unpalatable rubbish were 'got up' and shipped to this country, and are now being offered to consumers as dust, good fannings, and leafy Congou. We have subjected most of these teas to careful tasting, and are strongly of opinion that they are unfit for human consumption, and are surprised that the Government Inspectors have allowed them to pass into the hands of the wholesale dealers; further, we have no hesitation in affirming that teas of a similar description would have been seized and condemned when the Adulteration Act came first into operation."—*Home and Colonial Mail.*

INDIAN TEA AND THE AUSTRALIAN MARKET.

It is not, we think, unreasonable to expect that the extremely moderate range of prices for all teas of Indian growth which now prevails should, as a natural consequence, lead to a great increase in the consumption, not only in the United Kingdom, but in new markets. We are curious to hear how far the demand for Indian tea is affected in Australia by the low value of the produce offered. It is estimated that a market for fifteen million pounds of tea might be looked for in Australia if Indian teas were fairly introduced and appreciated. Unfortunately, the character of the Indian crop of 1879-80 has not been by any means up to the average, as even those most disposed (from their own interest in the produce) to take a favourable view of its merits have been compelled to admit the inferiority of the past season's manufacture; so that the conditions under which Indian teas have been introduced to the notice of the market in Australia have not been of the most favourable kind. This is to be regretted, as, with the growing figures representing the output of tea in India it is very desirable that new markets should be found for it, especially when it is borne in mind that the present yield of tea from the 200,000 acres of land estimated to be actually under cultivation, is not much more than 2 maunds of tea per acre of cultivation, and that a crop of 40 million of pounds, if that is reached next season, would only represent the moderate return of 200 lb. (or 2½ maunds) per acre all round. If, however, as we have a right to expect, Indian teas only keep up their well-earned repute, an appreciative market will always be found for them.—*Ibid.*

THE NATURE OF THE PRESENT DEMAND FOR INDIAN TEA.

Not the least remarkable feature in the present state of the Indian tea market is the depression in the value of the higher classes of the produce. We doubt if such a state of things has ever before occurred in the history of tea, when ordinary Souchong was worth within 2*d.* or 3*d.* a pound of well-made Pekoe, full of tip, as it is at present. The great bulk of Souchong sold within the last fortnight has realised from 1*s.* 1*d.* to 1*s.* 3*d.* a pound, while Pekoes for the most part, during the same period have ranged from 1*s.* 3*d.* to 1*s.* 6*d.* a pound, such well-known marks as Assam Co. and Bishnath Co. being on a par with the rest in this respect. Good-looking Pekoe of these marks, wiry well made and full of tip, brings now only 1*s.* 5½*d.* and 1*s.* 5½*d.* a pound, while plain Souchong fetches 1*s.* 3*d.*

The explanation of the relatively low value of the higher class tea is asserted to be the little demand for this sort, owing to the widely extended sale of cheap tea. The retailer cannot afford to use so much of the better sort of tea, and, in search of a profit is obliged to make the bulk up with the cheapest kinds, using less of the better grades. Hence the standard of the tea offered for retail sale is lower, and, as a consequence, Pekoes are in less demand in Mincing-lane. Souchongs and all the lower grades are benefited by the demand for them, while the commonest varieties of tea bring good prices now-a-days. The usual order received by the dealer from his country customers now is:—"Buy me as cheap a tea as you can get for bulk, with a little of the best kind that is to be had for money to flavour the rest with." This being the case it would seem as if the usual care hitherto taken in the sorting of the crop into several classes would be unnecessary in future, and that fewer sorts would be a better policy, not only for small concerns, where less division means larger breaks, but even for larger concerns. The public having become accustomed to low priced tea, is not likely, we think, to return very soon to high prices; and the manufacturer must study to meet the demand on the part of the public for "cheap tea," by striving to put as good quality in the shape of Souchong and Pekoe Souchong, into the market as he possibly can, relying for profit more on economy in working, and less on the price to be brought for a few samples of high-class Pekoe.—*Ibid.*

INDIAN TEA.

Apropos of the remarks on the keeping qualities of Indian tea in our last issue, we may observe that we opened a 10-pound box of very ordinary Pekoe Souchong the other day. The tea had been made at the very beginning of the manufacturing season of 1878, so that the contents of the box had been hermetically closed for about a year and eleven months. The tea had been manufactured in the ordinary way, and had been rolled and sorted by machinery, and it had not been panned. The tea was simply delicious for drinking, and to our taste had mellowed and improved by keeping, in fact we have frequently dark tea at 4*s.* per pound at home which would not approach this Pekoe Souchong in flavour. Pekoe Souchong of the same break as the tea we are alluding to probably fetched 11 annas (if so much) in the Calcutta market in 1878. If Indian tea will keep, and improve by keeping, for close on two years, it seems to us that the same article if fairly treated ought to remain fresh and continue improving for several years more.—*Darjeeling News.*

INDIAN TEA IN AUSTRALIA.

The following extracts, taken from a letter written by a gentleman at Sydney to a large Calcutta firm on the subject of tea at the exhibition, will doubtless be read with much interest just now.

"We have not been idle, sales are going on. P and S seeing that nothing was to be got from C, owing to the unfortunate relations between him and the Executive Commissioner of the exhibition determined to see him ourselves. He fell into our views at once and heartily. We have got a splendid show now on the basement, right under the dome and in front of the Ceylon Court. We made a very strong semi-circular table out of old packing cases and covered it neatly with green baize. Then P made up a multitude of sample packets of 1lb. each stylishly got up with a printed label, and we are selling a good deal daily. The whole expense is very trifling as we did most of the work ourselves. * * * * We are now printing 500 pamphlets to cost about £25 and will distribute these. You will not have to pay all this as T and I will be content with a bare commission, and we well try to remit you as near your invoice price as possible. We have got a young woman, the wife of the attendant in the Indian Court, to sell the tea on a commission of 3*d.* a packet. Many inquiries are now being made about the tea and it is coming into favour. My friend Mr. C. Moore, Director of the Botanical Gardens has placed his museum at my disposal, and if we see fit we may invite the best of the people here to an afternoon Indian tea there, before the exhibition closes. This only if sales should not come up to our expectations. One of our fellow judges, a Mr. Cooke, of Bathurst, a wealthy retired miller and grain merchant, is enamoured of our scheme, and is willing to put down £1,000 if we can get two others with £500 each. He would make P manager and give him one share. Start with good premises, a delivery man, and advertise well."

THE CUSTOMS AUTHORITIES AND BAD TEA.

The Customs authorities are at length waking up to their duties with reference to the bogus tea which has been foisted on the London market lately. Some thousands of pounds of this stuff have been seized and condemned. The Board of Customs are charged with the examination of all teas arriving in this country, and its officers have the power to open packages in bond, and to carry off for analysis samples of any tea they may suspect. Either tea is sent to this country in a very pure state as a rule, or else these officers are not very zealous; for only 47 samples were reported to the authorities as bad or doubtful last year, although about a million packages of tea pass through the bonded warehouses of the London and St. Katherine's Dock Company alone, to say nothing of the other bonded warehouses. Of these 47 packages six only were condemned as unfit for food. Such a high state of commercial morality is apt to excise apprehension lest some of the many parcels which have been passed as sound may have been defective. It is satisfactory, therefore, to find that the officers are opening their eyes wider.

CHINA TEA.

Mr. Herbert Townend of 16, Mincing-lane, writing to a comtemporary, says:—"I am not surprised, from past experience, that the idea should be pretty general in this country and on the Continent that our present quotation for common Congou (11½*d.*) is due to speculation, and will soon collapse. If it had been simply caused by, and depended upon, speculation, I should decidedly be of the same opinion; and although it is true that tea advanced in price at the commencement of September last, at the time that a speculative mania in all produce, &c., seized the community at large, yet for the position of tea it certainly would have risen in value a month or two

later had no such rise in other things commenced; in fact, buying common Congou in China at 9*d.* (when the price here was 8*d.*) on speculation, commenced a month before our market rose at all, as it was evident to importers there that the time at last had come when demand for this class in England had quite outstripped the supply. This being the position of common Congou, I think that it will not only keep its present price, but may advance, unless something unforseen occurs to stop its consumption, and I would almost venture to predict that it will be pence higher before its supplies can be increased to meet its present enormous consumption.

"Now, the facts that bring me to this conclusion are, in the first place—the Chinese must keep it up. It is well-known that last year they had determined to put a stop to the losses they had been incurring the last few years in selling the bulk of their crop of tea under 1*s.* per lb. The commercial Chinese are not like a good many of the English trading community, who care nothing about their own ruin if they can only bring down those who are doing well with them. Thus, if A is doing well, and advertises good tea at 1*s.* 8*d.*, B advertises it at 1*s.* 6*d.*, till at last the retail canister is brought down to such a price that no honest trader could pretend to offer for sale the qualities described by these advertisers of tea at "merchants' prices." But the Chinese are very different, and to use a common saying, they "knock their heads together and make a price;" and if foreigners won't give the price they can't have the tea. Until within the last few years foreigners did give the price; and when at last, through repeated losses, they refused longer to do so, they (the Chinese) began to reduce supplies of the class that lost the most to producers. Now, here is the whole secret of the present price and scarcity of clean common Congou. Consumption has increased enormously on this class in this country and in Russia, through economy and other causes being at work, till we find to-day that to every twenty chests of good and fine tea we sell 100 chests of common. It will be seen by this, as regards this class of tea, we are "burning the candle at both ends"—*viz.*, short supplies, with an increased consumption.

"What about the future? I believe common Congou will rule high, and good and fine grades of Congou will only just keep their head above the quotation for such, and the relative value will alter materially unless the public give more, which, I believe, they will be very slow to do. Under these circumstances, I quite agree with you in advising the retail trade to lay up in store good, sweet, common tea (all grades and descriptions) under 1*s.* 2*d.*, as circumstances not only justify at present, but point to much higher prices for this class. There has been a great demand for sweet Congou tea "for price" through the whole of this season, which has cleared off every chop out of importers' hands directly upon arrival of ships, showing that importers held no stock. And again, we have no old seasons, as in former years, to help our supplies; and it is well known that speculators hold very little of this description, as the rush by them was upon good to fine teas, which sorts will be kept firm by the steady advance of common grades. We have also another very serious element to contend with, *viz.*, shipping demand. Shippers have refrained from buying the last five months, and stocks are very low all over the Continent, and they must buy in the spring at the latest. From whence are they to draw their supplies for common Congou? Competition is not so keen on the Continent as in England, profits are larger, and sixpence advance would not be a great advance for them to pay. We have also speculators who, having during the last few months made money upon produce, will eagerly watch tea and all produce for an opportunity to join again, and as we all know common Congou is considered the "Consols" of the tea market. Under these circumstances I would certainly, with you, advise all who can not to let outside men have all the profits, as they certainly will, unless the trade steal a march upon them by laying in stocks.

"Before I close I would like to say one word upon the foolish reports about tea arriving unfit for human consumption. As a large buyer of tea, and consequently having the opportunity of seeing almost every chop of tea that arrives from China, I can confidently state that I believe there has scarcely been a single parcel of Cactus, Maloo, or any description of "lie" tea arrive in this country since the Government appointed an "Inspector of Tea;" and I believe the reports that are spread about tea arriving unfit for consumption are false, and that the public need fear no harm from any tea that is now offered for sale—so far as being injurious to health. It is true that very common grades of ordinary Congou, Caper, &c., are more like physic than anything else to drink, and cannot do the grocer any good in selling them, as people like a refreshing beverage, not a nauseous medicinal-flavoured drink. I would strongly advise the retail trade to avoid buying altogether such low-class tea, the flavour of which no blending can kill, and thus prevent its importation."

THE COST OF TEA.

In these days of low averages for all sorts of Indian grown teas (the exception of one or two remarkably fine flavoured lots of Darjeeling growth, which have brought extreme prices, only serves to prove the rule) it is becoming a matter of more and more consequence to study the question how to produce the crop at the lowest possible cost.

The cost of production varies naturally, not only according to the district in which the cultivated area is situated, but also according to the precise position of the estate in the district in question.

Some tea districts of India, notably Darjeeling and Kangra, are much better placed for procuring labour than the districts of Assam and some parts of Cachar; while other parts of Cachar and Sylhet again have the advantage in this respect over most parts of Assam.

As a rule, in every district nearness to bazaars, villages, roads, and rivers makes an important difference in the facility with which labour is obtained and kept on the estate, and, therefore, in the cost of producing the crop of tea. It has become necessary to consider the question whether the present system of offering a high bonus, or, indeed, any bonus at all, to a well-paid cooly to induce him to accept a fair day's pay for a fair day's work is not radically wrong; and if it can be stopped by general agreement—as we think it might be—one heavy tax on the tea industry would be removed.

It will then have to be considered whether, as a rule, a slight addition might not, without any hardship, be made to the present daily task of the cooly; for of course it will be seen at once that where a body of men is concerned, any extra work performed by each would, in the aggregate, make a considerable difference both in the cost as well as in the time of getting through a specified job.

In Darjeeling, we believe, no such thing as bonus payments to coolies has ever been made, and, although there is every year a greater demand for labour—rates have not been much enhanced on the tea gardens, although the contractors for the Steam Tramway Company have, as is usually the case in their urgent demand for cooly work, been compelled to pay much higher rates than those which prevail in the tea gardens. Assam is, with good reason, generally considered the most expensive district so far as cooly labour is concerned, owing, not only to the long river journey which coolies have to make to arrive there, but also to the unusually high rates and cost of all the necessaries of existence. Coolies are, too, more unwilling to remain and settle down, we believe, in Assam than in Cachar and Sylhet, which are, so to speak, nearer home for them. In Assam, however, owing to to the larger yield per acre in some cases, and to the attention paid to economy in others, we understand that some concerns are able to place their crop of tea in the Calcutta market at the average rate of seven annas a pound, inclusive of all charges for freight and agency; while we have heard of some London companies who lay down their teas in this market, inclusive of every item of cost, at the rate of one shilling a pound. If these things are done now by a few concerns, the time is probably coming when what is now the exception may become the rule; and we do not doubt that our readers will find it well to consider how far it is possible in their case to work, so as to lay down their tea in London at a shilling a pound after defraying all charges.

In the event of the hoped-for improvement taking place in the price of tea, their position would be none the worse; while, if the present low rate continue in force, the result of working on the scale to which we have directed attention, would be the avoidance of some disappointment and loss.—*Home and Colonial Mail.*

COFFEE.

The Imports of Coffee into Spain in 1878 were 3,092 tons, an increase of 797 tons over 1877. The imports of cocoa were 4,937 tons, or considerably more than those of coffee, but both figures are trifling for so large a population as that of Spain.

The Liberian coffee in the Soldier Gardens continues to thrive, and Colonel Hawkes, the indefatigable Honorary Superintendent, hopes in his next annual report to give some estimate of the probable economic value of this description. The plants in the Agri-Horticultural Gardens are also in a satisfactory condition. Considering the high prices charged for coffee in Burmah, even if it cannot be successfully grown for exportation, we might surely be able to raise enough to supply local wants. The price in our bazaars is usually higher than the English retail price, although we are so close to the Ceylon and Neilgherry plantations.

Curing and Shipment of Coffee.—The various mercantile firms in Madras, and some of the principal agencies in the mofussil, are now very busy curing and shipping the large consignment of coffee that are being received daily from the European and native planters on the Shevaroys, Pulneys, and Neilgherry Hills. The outturn of crops this year is unprecedently large in comparison with the quantity realized in former years, for some of the estates, especially in Coorg, have as much as seventeen or eighteen hundred tons ready for despatch to the various coffee works in the presidency.

The visit of Dr. King to Java, has led to the discovery among other important facts, that the Java planters have been very careful in the selection of their cinchona seed, and that the superiority of their bark is to a large extent due to the fact that they grow good varieties more extensively than we do. This is a point in planting which is frequently lost sight of; we go in for the cheapest seed, forgetting that what is a little more expensive at first may prove most profitable ultimately. The same was done in many of the tea districts. In the North-West, where the Government tried experiments

at a very early date, we find nothing but the very commonest of China plants. This was of course brought about by another cause. The Assam variety was practically unknown at the time these properties were opened out, and seed being consequently purchased in China, it was natural that the Chinese should not be disposed to give their best varieties. Now, however, the case is vastly different and in extending and refilling in, in all gardens, whether tea, coffee, cacao, or cinchona, the greatest care should be had to the seed, and only that quality should be planted which experience has taught us will give the best results. In the larger gardens of Debra Doon where an all-round outturn of 464lb., per acre was obtained in 1878, the price realised was only 9½ annas per lb. Now, the advantages which those gardens enjoy in the matter of labour, are such that this tea was produced at a cost of six annas per lb., and had the quality been Assam Hybrid, the average value would have been much higher, with only the initial cost of seed to add to the expenses. Now, that we know the best quality of bark to grow (*C. Calisaya*), planters should go largely in for it, and not waste their time in planting land with inferior varieties, whose only qualifications are that the seed costs less, while the produce is immensely inferior as to quality.

DATE COFFEE.

A COMPANY has been formed in London, with a capital of £50,000 in £5 shares, In the language of the prospectus, to "purchase and work the English patent for the purpose of manufacturing abroad, from the date fruit, a substitute for coffee." This document goes on to say that "the vendor assigns his English patent for £2,000 in cash or shares, at the Directors' option, and 1*d.* per lb. royalty, the Directors having power to purchase the royalty. A mixture of three-fourths of date coffee with one-fourth of coffee makes a purer and more delicate drink than if made entirely of coffee, and it effects a saving of two-thirds; whilst even if no coffee is used, a much more refreshing beverage is produced from date coffee than from common or ordinary coffee. An ounce of date coffee and a quarter of an ounce of ordinary coffee, without any chicory are sufficient to make four 8-oz, (or ordinary breakfast) cups of coffee. Intending shareholders are invited to call at the Company's offices and taste this beverage before investing. Upwards of 100 persons are stated to have done so, and they are unanimous in their opinion as to its superiority. Letters have also been received from persons resident in the country; amongst others, one from Mrs. Blackall, copy of which is below.

The letter from Mrs. Blackall is as follows:—

Copy.

6, Sussex Terrace, Southend, Essex,

31st January 1880.

DEAR SIR,—I have to thank you for the sample of date coffee you kindly sent me as requested. My husband, Colonel Blackall, and I tried it as directed, and pronounce it very good; we can safely recommend it in every way. How wonderfully it will reduce the price of coffee, so that the public will be greatly indebted to you.—Wishing you every success, I am, yours truly,

(Sd.) FLORA BLACKALL.

P.S.—You may make any use of this you please.

The calculations of profit made are comparatively simple. "Mr Henley's estimate," says the prospectus, which is annexed, shows that if only twenty tons of dates are to be treated per week, it will leave an annual profit of £18,500. By manufacturing sixty tons per week the profit would amount to about £50,000 a year, or 100 per cent. per annum, even supposing the whole amount of capital were called up."

All this looks so rosy that coffee planters will no doubt feel somewhat startled. They need not become seriously alarmed, however. It is astonishing how clear everything appears on paper, especially in the prospectus of a new company. There have been several substitutes for coffee introduced at various times, but the famous berry still holds its own. We notice that under the head "Directors," the name of the Chairman only appears. This gentleman is Mr. Henry Hayman, formerly of the Don Pedro North Del Rey Gold Mining Company, and it is mentioned that this mining company, paid for several years a dividend of 100 per cent. The analogy between gold mining and making a substitute for coffee from dates is not sufficiently apparent to prove effective.

HOW COFFEE WAS DISCOVERED.

WE read a quaint story concerning the discovery of this favorite beverage. Toward the middle of the fifteenth century, a poor Arab was travelling in Abyssinia, and finding himself weak and weary from fatigue, he stopped near a grove. Then, being in want of fuel to cook his rice, he cut down a tree which happened to be full of dead berries. His meal being cooked and eaten, the traveller discovered that the half-burned berries were very fragrant. Collecting a number of these, and crushing them with a stone, he found that their aroma had increased to a great extent. While wondering at this, he accidentally let fall the substance into a can which contained his scant supply of water. Lo, what a miracle! The almost putrid liquid was instantly purified. He brought it to his lips; it was fresh, agreeable, and in a moment after the traveller had so far recovered his strength and energy as to be able to resume his journey. The lucky Arab gathered as many berries as he could, and having arrived at Arden, in Arabia, he informed the Mufti of his discovery. That worthy divine was an inveterate opium smoker, who had been suffering for years from the effects of that poisonous drug. He tried an infusion of the roasted berries, and was so delighted at the recovery of his own vigor that, in gratitude to the tree, he called it *cabuah*, which in Arabic signifies force. And that is the way in which coffee was discovered.

THE TRAVACORE COFFEE CROP OF 1880.—We have received the following assuring intelligence from an esteemed correspondent in South Travancore:—"We are having splendid rain in these parts, and I hope the bumper year is at hand. Places look remarkably well, and now that the seasons have changed, I hope a new era has commenced, and that the future of coffee will be as bright as the prospects of this coming season." To this we have to add the information which we are receiving on all sides to the effect that in the most backward estates all over South Travancore the blossom has set in in a manner and with a freshness and fulness, which promises golden returns, if only one or two more timely showers fall within the next fortnight. We sincerely trust our correspondents' prognostications will prove true.—*Western Star.*

MAHOGANY PLANTS IN BURMAH.—Great success has attended the experiment of planting mahogany in the Government gardens here. Colonel Hawkes, the Superintendent, says, of 112 plants raised from seed sown in September 1878, not one has failed. Some that were measured when exactly a year old were from 6 to 8 feet in height with a girth of over three inches, a rate of growth altogether unprecedented even in the case of indigenous trees. In addition to its rapid growth, the mahogany tree appears to be very hardy, thriving in the poorest soil and promising to bear with impunity the extremes of heat and moisture, characteristic of the Burmese climate. It seems strange with Forest Department in the province, and a host of highly paid professional foresters, we should get this information about mahogany from an army Colonel who only interests himself about the soldiers' gardens in Rangoon. Liberian coffee is also thriving here, both in the Government gardens under Colonel Hawkes and the agri-horticultural gardens in town. The heavy rainfall on the 1st and 2nd November, when eleven inches were registered, destroyed the early operations in the vegetable garden, and so retarded subsequent planting as to make the outturn small and inferior. The vegetable season here is particularly short, being limited to about three months from November for the English descriptions, although the Chinese with manuring plentifully manage to raise them a little longer.—*Rangoon Correspondent of the Statesman.*

FURTHER correspondence on the Coffee Leaf Disease has recently been issued, and includes communications from a number of persons official and unofficial. We do not propose to discuss the subject at present, but we would point out two impressions left on us by a perusal of this correspondence. They are—1st, the failure of the sulphur cure, and 2nd, the fact that all efforts seem to be confined to seeking a "cure." There can be doubt but that the sulphur cure has no effect. One expert, Mr. Wm. Cameron, says pointedly:—"The result is most conclusive, that sulphur is of no practical use." In a few of the letters we are told of various successes achieved by the sulphur and lime cure advocated by Mr. Morris, but they all end in agreeing that the benefit is exceedingly transitory, and that the disease seems to come back with greater force than ever.

In considering the second impression, we are partially in a position to throw some light on the first. A great deal of time, attention, and money has been bestowed on the consideration of a cure, but little or nothing appears to have been done towards investigating the cause. Hence it seems to us that the many curative agents suggested have all proved more or less transitory in their effects. If we wish to eradicate a disease, we do not content ourselves with outward remedies, calculated to reduce the pain. While not under-rating the importance of that, we at the same time endeavour to ascertain how Nature's immutable laws have been infringed and the disease brought on; because disease is the result of a breach of Nature's law either voluntary or involuntary on our part. And in the case of this leaf disease, both in regard to coffee and to tea—for they are more analogous than appears at first sight—the first thing we ought to inquire is, Does our mode of cultivating interfere with, or thwart in any way, Nature's ordinary mode of growing the plant?—and we think few intelligent planters will fail to find that we do not grow those plants as Nature does. If, then, the exigencies of the trade require this peculiar treatment, should we not do something by way of assisting the plant to bear up against the unnatural treatment? Here we altogether fail, and confine our attention to endeavouring to mitigate the evil results of our neglect. What we ought to do is to strengthen the plant by nourishing the root, and, by a very much improved mode of cultivation, assist the outraged plant by neutralizing the effects of our peculiar treatment.

COFFEE PLANTING IN SUMATRA.

AROUND the bases of the mountains, and on other elevated land are considerable coffee plantations, the quality of whose productions is undeniably high, and compares favourably with that of other countries. The highlands of Sumatra are eminently suited for the cultivation of coffee, and the land is as fat as it well can be; so that, notwithstanding that some traces the leaf disease, which has of late years caused such disaster in Ceylon, have recently made their appearance, they have a great future in store. At present there are very few private European growers, the principal planting being done by natives; and although there is anything but energy visible in the country, very considerable quantities of coffee find their way to foreign markets, which are principally American. Only recently a ship left Padang for New York, with a single shipment of nearly one million pounds on board. Whilst the extensive highlands of Peraks, in the Malay Peninsula (recently inspected, by the way by a well-known coffee planter from Ceylon, in search of new ground), are still uncultivated, it is hardly to be expected that English planters will take refuge under a foreign flag; but there is undoubtedly a splendid opening for capital in Sumatra, be it Dutch, English, or of any other nationality. The Government is favourable to the interests of improvers of its colonies; but I fear a great blow has been dealt in the wrong direction by the recent introduction of heavy taxes and duties. I cannot speak for other years, but this season I have seen coffee trees subjected to anything but superlatively close attention, with their branches loaded with berries to repletion. On private plantations the wages range, from forty to fifty cents. (of a guilder)—*i.e.*, eightpence to tenpence—per day—which is higher than the general Ceylon average, but private planters are very few in number. The great bulk of the coffee produced is known as Government coffee, which is the result of a compulsory cultivation on the part of the natives. Each native of fifteen years and over residing in the highlands, is bound to plant and cultivate each year fifty coffee trees, and he is also compelled to sell the produce to the Government, and to no other person, at the upshot price of 14fl. (23*s.* 4*d.*) per picul (133½lb. English), delivered at the Government coffee pack-houses, as they are called. As the coffee fetches at public auction 60fl. (90*s*) on an average the profit is something considerable.

At the first blush it seems very hard to first take a man's country against his wish, then make him grow a plant he does not want to, and finally compel him to sell the produce thereof at a quarter of its value. But a very short residence amongst the Malays will reconcile anyone to such a condition of affairs. Into the question of right to take another man's country because he cannot help himself, I will not enter, leaving it to deeper thinkers than myself to decide whether the proceeding is justified by the defection of the uncivilised in not attempting to employ the benefits Nature has so bountifully placed in their grasp. I only know that, left to themselves, the natives, of those particular regions, would never cultivate a single pound of rice beyond what they required for filling their own mouths, whilst coffee they would never cultivate at all; their own ideas of agriculture never reach beyond a clump of plantains here, a few cocoanuts there, and a patch or two of rice. Here it is no great hardship to have to grow coffee. If a man requires land, he has only to go outside his door to find as much as he wants, whilst the suitability of ground is such that the least amount of attention is repaid a hundredfold. Besides this, the natives are exempt from taxation of every description unless compulsory labour known as "Heerendienst," the non-fulfilment of which entails a fine, can be so classed. "Heerendienst" is compulsory labour on the roads, when such require repair; but no man can be made to work for more than one day in each week. This also I cannot but regard as a salutary antidote against the innate laziness of the Malays, the effects of which are nowhere more apparent than on such ways as they themselves use for private purposes. Paths into the woods are deviously conducted round insignificant stones and fallen timber, the removal of which would not occupy an hour, but, although dozens of persons pass during the day, no one can find sufficient energy to remove the obstruction.—*The Field.*

COFFEE IN COLOMBIA.

IN the Consular Report for Panama (Colombia), in 1878, the following occurs:—"In the Department of Chiriqui, in the interior of this State, coffee planting has been recently introduced by one or two enterprising persons, with every prospect of the most gratifying results. As yet, only a small portion of land has been cultivated with this valuable product. One gentleman planted 70,000 coffee trees three years ago, from which he will get his first crop in the ensuing year. The fine rich lands lying along the slopes of the mountain ranges in that portion of the State are most admirably adapted for coffee culture on an extended scale. The climate is cool and very healthy, and the land can be obtained for nothing. There is also steam communication from Panama by coast and river to the heart of the district—the distance being about 300 miles—by which the produce can be readily and cheaply conveyed to this port. To young men in over-crowded England who can command a capital of from £2,000 to £3,000, and who are not afraid of a little roughing it at first, coffee planting in the district of Chiriqui offers a fine field of enterprise, which could not fail to produce to the investor, in three or four years, a most lucrative and yearly increasing return. The life is a healthy and enjoyable one, and sufficient labour is obtainable at reasonable rates. David, a good town of some 3,000 inhabitants, is situated in the centre of this district, about forty miles up the river of that name, to which place good steamers run from Panama every fortnight. Large herds of fine cattle are also bred on the extensive savannahs, which stretch away for miles around the town, considerable numbers of which are brought by steamer to Panama, to supply the city and shipping."—*Home and Colonial Mail.*

CINCHONA.

THE ENCOURAGEMENT OF CINCHONA CULTIVATION.

A MORE malarious country than India, we suppose does not exist on the face of the globe. European sojourners in sunny Ind have been laid low in thousands by fever, and it has thinned the ranks of our armies more completely than all the engagements those armies took part in since the British set foot in the country. For years past the most distinguished physicians have been employed in discovering some sure and cheap febrifuge. We remember the time, not so very long either, when "cupping" was the popular remedy resorted to in fever cases, and we shudder to think how many fell victims to the ignorance of the faculty. Quinine or Peruvian bark as it used to be called, soon however asserted its valuable properties as a febrifuge, and ever since, the quantity of quinine used in the Civil and Military Hospitals in India has been very considerable. But America was the only cinchona-growing country, and the importation of the bark proved very expensive. Botanists were of opinion that Cinchona could be cultivated with success on certain of the hilly ranges in India, and the Home Government decided to attempt the naturalisation of the famous bark tree. This was not quite so easy a matter, as the event proved. Mr. Clement Markham, the eminent botanist, with competent assistants, was deputed to proceed to America, and explore the forests of Peru for a quantity of seeds and plants. This was in 1861. The record of their experiences cannot but be read with thrilling interest, and as we read of their hair-breadth escapes we almost fancy the pen of DeFoe, or Mayne Reid, was employed on the task of telling the story of how the fine cinchona trees now flourishing on the slopes of the Neilgherries, were brought from their native home. Not only did the explorers experience dangers in the Peruvian forests, but the people and Government of the country opposed the exportation of plants and seedlings to the utmost in their power. But Markham and his colleagues at length accomplished their difficult task, and in the year 1863, the first cinchona nursery was opened out at Ootacamund on the Neilgherries. Now, whole forests clothe the slopes of the Neilgherry Hills, as well as those of Sikkhim, Assam, &c. To the late Mr. William Graham McIvor, the first Superintendent of the Ootacamund Cinchona plantations, must be accorded the credit of making the cultivation a success. But still while the Government have a sufficient quantity of bark, at a cheap cost, for medical consumption in the country, the febrifuge is not placed within the easy reach of the people. It is true that a very cheap concoction is manufactured from the various alkaloids of the bark, and sold to the public, as well as being kept in hospitals, but something more is wanted. We have before us now an order of the Madras Government, directing that a letter from the Collector of South Canara regarding the efficacy of Neilgherry cinchona bark in the treatment of fever, be circulated to all Collectors. We have not seen the letter in question, though we have no doubt that it will tend to make the efficacy of cinchona bark more widely known. But what is required is that the *cultivation* of the tree should be more encouraged. Villagers, ryots, &c., should be induced to put down a few plants round their houses. By this means a cheap and simple remedy for fever will always be within the reach of the rural population who live at a distance from hospitals and dispensaries. It is well-known that planters prepare a decoction from the cinchona bark, which is a reliable remedy in simple case of fevers, and the most ignorant native could be taught to do the same.—*Athenæum.*

CINCHONA CULTIVATION IN JAVA.*

IT is scarcely necessary to say that the climate where the cinchona flourishes best in Java, *viz.*, at a heighth of 4,000 to 6,000 feet is the most delicious for the European; there reigns an eternal spring, a medium temperature of 60 deg. Fahrenheit. When we look around, in place of the gloom of the forest, we see the regular lines of the cinchona trees. In place of the dark green of the great trees, the ruddy color of the succirubra or the light green tint of the ledgeriana plants. In place of the impenetrable wilderness formed by jungle and "lianos," we see beautiful paths and a carefully weeded plantation. We will describe, however, the cinchona cultivation more in detail. The method now most in vogue in cultivating, is by sowing the seeds, but these being extraordinarily light and thin, much precaution must be taken to obtain it good. The seeds are sown above the ground, on virgin soil or fine sandy earth. To preserve the seeds from the heavy rain, or the hot sun, a raised covering is constructed of *alang alang*, and on two sides the beds are protected from the wind. Usually, if the seed is good, it comes up speedily, and after two to four

* Translated from the Dutch *De Indische Mercuur*, a useful paper published in Amsterdam.

weeks the first small leaves make their appearance. The "paggors" are taken away by degrees so as to accustom the young plants to the sun and air, but the "pajong" remains, because the sun would yet be too strong for them, but principally because heavy rains would wash the plants away. As soon as the plants become strong enough, *i.e.*—one thumb (Rhineland) they are planted out at a distance of half a foot (Rhineland) from each other in regular beds which are also covered. Some months after these covers are removed, in order that the growth of the plants may not be checked now that they have attained more strength and are in the open ground. Of course, if one has but few seeds, greater care will be taken in planting, but the principal care is to sow in good soft earth, and to see that it is kept of a regular moisture.

The cultivation of cinchona by seeds is excellent for obtaining a large quantity of plants; if, however, we want a special kind, a different course must be pursued. The cinchona very readily gives hybrids, not only from the different varieties, but from the different kinds also, so that it is difficult to get seeds upon which we can rely as of a specified kind. Above all, the Cinchona Calisaya has many varieties, and as to all of them there is as yet little clearness. The best variety of this kind is C. C. ledgeriana, which contains the greatest cinchona value ; next to this is the C. officinalis, which, however, cannot be compared to the best varieties of C. ledgeriana. The remaining kinds, such as C. pahudiana, which is very bad, the C. Hasskarliana, the C. Calisaya Javonica, and other Calisaya forms, the cordifolia, mecrantha, lancifolia, &c., are, for their quinine-value, not worth the pains of cultivating. The only one of which the bark is used by apothecaries is the C. succirubra.

The three kinds which must be cultivated are C. ledgeriana, C. officinalis, and C. succirubra. The last is easily propagated by cuttings, but as the seeds are usually pure, it is best to cultivate from them, and this also is the case with C. officinalis. It is different with the C. ledgeriana.

The first samples which were imported of this kind have been chemically examined, and it is remarkable how great a difference there is between the different plants and their quinine-value. Some sample contained not more than 3 per cent. of quinine, while others gave upwards of 10 per cent. It therefore became evident that the plants from seeds of this variety did not give equal results. There were forms which were very devious from the mother plant, so much so that they were thought to be hybrids. It was concluded to undertake an artificial increase by different ways of propagation by cutting, but the results obtained were so bad that the project was given up. The progagation of the ledgeriana and the succirubra has been tried in the open plantation and two or three grew passably well. Mr. Moens cut out the bark above and below the graft, and found the remarkable result that the bark of each was different as they came from different trees. One can therefore surely graft one upon the other without deteriorating the quinine-value. I find, however, that grafting is not always successful on the succirubra, and I therefore adopted another means.

I took some sets of growing roots of succirubra, grafted on them the ledgeriana, in the same manner as in Holland the aucuba and rhododendrons are treated, and placed them under double glass, and I have heard, from Mr. Moens that a part of them are flourishing. On this plan great quantities can be propagated ; and it must also be borne in mind that all kinds of roots can be used for this purpose.

H. OTTOLANDER.

CINCHONA BARK FOR DRUGGISTS' PURPOSES.

37, Mincing-Lane, London, February 12th, 1880.

(*From Messrs. I. A. Rucker and Bencraft.*)

THE buying trade is divided into two main sections, *viz.*, (*a*) the druggists, and (*b*) the manufacturers. Of these the last named are far the most important, and the orders arising from them overshadow t[he] more variable and less constant demand of the druggists. It will, ho[wever], be more convenient for us to consider the nature of those two dem[ands] in inverse order to their importance. We, therefore, take first :

(*a*) The druggists.

This portion of the trade may be said to buy on appearance only and with little re[f]erence to the analytical value of the bark. They dispose of the bark, wh[ich has be]en bought, in small lots, chiefly among the Continental chemists, who make from it various infusions, tinctures and decoctions, and even simply pow[]der it and sell it without further preparation as "Bark," or "Tonic Powd[]ers." For purpose of this sort, they do not go to the trouble and expense of analysing the bark to ascertain the real nature of its contents—the sm[]allness of their purchases in many cases rendering the porportionate cos[]t of the process far too heavy—but are content to judge what is presented [t]o them by certain traditional appearances and signs, which though no d[]oubt originally founded on guiding principles deduced from the results of a [n]umber of analyses, have now been warped or altered so far as to often fa[il] completely if depended on as guides to the intrinsic value of the bark.

We have, therefore, at t[h]e outset to face a somewhat anomalous demand, which puts a fictitious v[]alue on the presence of certain conditions, altogether, or at least in great measure, ignoring the richness or otherwise of the secreted alkaloids It is obvious that this is a state of things which must result in the giving of what may fairly be called fancy prices for bark of a certain description a[n]d *primâ facie* such prices should be eagerly sought after. We will proceed now to explain the peculiarities on which such stress is laid, and then attempt to determine how far it is to the profit of the grower to aim at securing and preserving their presence when preparing the bark for market.

First, as a general principle, it may be laid down that anything which is symptomatic of care in the preparation of the bark, is accepted as favourable evidence ; and evidence of some sort is required by the chemist, not only as to the qualities of the bark, but also to establish its actual identity. The fact that no analysis is attempted affords great facilities to the passing off of other bark worked up to resemble cinchona in taste and appearance, and the first doubt to be satisfied is as to the identity of the bark. Admitting that to be satisfied, we come to certain requirements for show purposes. Bark is wanted for exposure in the window, and the public have to be convinced of its medicinal properties by outward and visible signs. Again, as the chemist wishes to avoid any elaborate working out of the raw material, he requires bark which will readily yield enough of its contents to give to his preparations sensible tonic qualities. Lastly, he wants bark which, while it fulfils these conditions, does not possess stores of the higher alkaloid which he cannot extract by his rough and ready process, but which would increase the price he must pay.

Reducing these generalities to a more detailed form we find that the chemist wants (*a*) a bark possessing what is to his mind undoubted evidence of belonging to the tribe of the cinchonidæ ; (*b*) a handsome bark for show purposes ; (*c*) a bark which will readily yield a good proportion of its contents ; (*d*) and which does not possess stores of valuable alkaloids useless to him.

It is plain that the succirubra meets this last requirement better than the more valuable officinalis. It sometimes happens that the large druggists are obliged to buy officinalis. When this happens, they usually re-sell the bark, after extracting by their method a part of its contents, to the manufacturer, and it not unfrequently happens that the bark proves to be just as rich in quinine as it was before it had been subjected to the treatment of the druggist. His method fails to effect the comparatively insoluble quinine, while it extracts a proportion of the lower alkaloids. It is obvious then that the chemist does not want a valuable quinine bark, but rather a soft red bark like the succirubra, rich in total alkaloids, which are separable by his method, but comparatively poor in the obstinate and unyielding quinine. It is true that even the lower alkaloids are not completely extracted by the process he uses, but they yield to infusion sufficiently to justify him in styling the result a tonic mixture. Its actual medicinal value must vary according to the care and trouble expended on its manufacture—if indeed such a term may be applied to the process—in each individual case.

As a cheap bark, but yet rich in the more easily separable tonic and febrifugal matter, the succirubra may then be rightly termed *par excellence* "Druggist's Bark." Nor is it deficient in the other attributes required by them. A larger tree than the officinalis variety, its bark shapes into a larger, and therefore to the uninitiated eye, a handsomer quill. The appreciation of the quinine manufacturer of the beauty of the deeply marked and scored officinalis bark would seem to be an acquired taste, and resultant on his educated knowledge of the properties it contains ; for the chemist finds the eye of the public attracted rather by the silvery coated but smooth surface of the stout stem red quill.

We may then accept the fact that not only is the succirubra bark at its present price preeminently fitted for druggists' use, but even if the value of the officinalis were to decrease it would still be unsuited for a trade which aims at holding the contents of the bark *in solution* and not at working them out into a pure *precipitate*.

With this premise we may proceed to particularise the point in the appearance of the bark, the general nature of which we have already determined. They are—

(1.) *The boldness and fineness of the quill.*

Stout stem quill from fully matured trees is required.

(2.) *The regularity of the roll of the quill.*

The double roll finds most favour. It should be uniform throughout, and there should be no knobs or knots in the bark.

(3.) *The length of the quill,*

which cannot be too long, though if otherwise suitable ; quill from a foot onwards in length may be termed "Druggists' Quill."

(4.) *The evenness of the parcel.*

This is obviously of considerable importance since it is brought by appearance, but provided there is no absolutely short broken quill, it is of less moment than the conditions mentioned before.

All the points so far alluded to may be classed under the general heading referred to above, as evidences of care in the preparations of the bark, and they therefore indirectly testify, for the satisfaction of the chemist and his customers alike, to the identity and, as a necessary corollary, to the medicinal virtues of the bark. Their presence in combination will also go far to secure the value of the bark as a show specimen.

But we have now another point to mention, to which tradition has given a fictitious importance. That is—

(5.) *A silvery coating of the epidermis of the bark, and if possible the presence of crustanaceous and stringy lichens.*

No doubt the silvered bark is peculiarly adapted for show purposes, but the value placed upon this condition of the epidermis is too great to be accounted for solely in this way. It is prized rather because tradition has not altogether unwisely declared it to be together with the bitter taste of the

bark, the great safeguard of the chemist against deception and the strongest proof of the indentity of the parent tree.

We have before us at this moment a beautiful specimen of prime druggists' bark bold, stout, long, well-grown, double rolled stem quill. Its intrinsic value as a quinine-producing bark is about 3s. but it fetched at public sale no less than 4s. 6d. But for some reason or other, though there are evident signs of the existence on it at some time of a complete silvery coating, it has been carefully scraped and denuded of the adherent matter. This was, no doubt, done for some good reason, such as the presence of a parasite or the mouldiness of the coating, but there is little doubt that its enforced removal depreciated the value of the bark by a considerable percentage; indeed an almost identical specimen but beautifully coated realised in a market, somewhat lower in tone, as much as 4s. 10d.

We see now why, to quote our own words, which were lately misunderstood, stout stem bark "must never be sent flat to market," for, if so prepared it would at once lose its chance of realising, on the strength of its appearance, a price far in excess of its intrinsic value.

To ensure its arrival at the home market in the condition we have described, bark likely to command the attention of this portion of the buying trade must be most carefully prepared and packed; and this opens up the further question as to how far it is to the profit of the grower to attempt to meet the requirements of, and in return command the rates given by this section of buyers.

We have already stated that the druggists' demand for bark is but a small one as compared with that of the manufacturers. This drawback is a factor in the question, the importance of which can be, in great measure, accurately determined. But there is a feature in this demand which is apt to upset all calculations; and that we have already referred to when we call it "variable and less constant." It is possible to depend on its presence. Orders from abroad may or may not have been received, and in their absence, the finest quill will fetch but its true analytic value, a value which would not have been impaired had it arrived denuded of its silvery coating, flat and in broken chips.

It may be urged that by holding over bark until the demand is present, this difficulty is easily obviated; but the remedy is not so simple a one as it appears. In the first place, it is a question whether if attention generally was directed to sending over druggists' quill to market, the amount would not exceed the demand. Further there is the expense of holding the bark to be considered a slight one, it is true, but still a factor in the calculation. Samples have to be redrawn and redistributed, and rent paid. And here again we meet a fact to which we have alluded before, namely that the buying trade is so small that their favourable disposition is a matter of importance. There is no doubt that there is on the part of the principal buyers for the manufacturers a strong feeling of jealousy towards any large buying in. We do not attempt to defend or even to explain this feeling, but its presence is an admitted fact. In a strong market, no doubt, it can be ignored, but in a weak one prejudice of this kind may materially affect a sale. If then, after holding over for some little time, in the hope of obtaining the fancy price, a retreat has to be made on the second line of the manufacturers, it may be found that the movement is not so successful as it would have been if undertaken at first.

However this may be, the variable nature of this demand introduces an element of uncertainty which is not encouraging to those who court it. But if present, it must clearly be understood that it results in distinctly fancy prices. Thus some magnificent Broughton quill, exactly suited for the trade fetched not long ago 4s. 6d. to 4s 8d. An eminent manufacturer commenced the bidding at 2s., and we have little doubt that analysis would prove it was not worth to him more than 3s. Again at the last public sales, held on the 10th instant, some very fine Darjeeling quill realized 4s. 1d. A similar lot, but not so fine in appearance, fetched 2/3, and after the sale the same gentleman we referred to above, told us the two lots gave almost identical analyses. Instances of this sort might be multiplied indefinitely, but we have said enough to shew how materially the value of the bark is enhanced, if it excites the competition.

But it must be remembered the additional rate obtained is not all profit. Picked labour must be employed to bark the trees, constant supervision is required in all the process of shaping, drying and packing, to ensure the presence of, and then to preserve intact, the characteristics required. Cases must be used instead of cheaper packing, the quills must not be pressed so as to be broken, not packed too loosely so as to impair their silvery coating through friction. All this to us on this side the water seems but a simple matter, but a Ceylon planter will tell us that it involves no small expense and labour.

How far then this expense and labour will prove profitable, must depend largely on the circumstances ruling the outlay. On the supply of labour at his disposal and even more on the average intelligence possessed by it will often hinge the advisability, or otherwise, of an attempt to secure these high prices.

On our side we can only point out the margin of profit to be gained, and leave to each individual to determine, how far that margin will be reduced and frittered away in the effort to gain it. But we can shortly summarise the results of many experiences, when we say that as a rule it is worth while undergoing the expense and trouble necessary to secure this market and that, too, notwithstanding the possibility of occasional disappointment, from the variable nature of the demand.

If then a planter has bark which is likely to shape into "Prime Druggists' quill," we advise him, under ordinary circumstances, to prepare it for market in such a way as to preserve in it the characteristics noted above and we believe that he will find his enterprise a profitable one, though not so much so, as he would be tempted at first sight to imagine, on reading the prices obtained.

Besides the fine quill bark, the druggists buy the small twigs, for they most readily yield their contents to unscientific methods. For this reason twigs must be packed separately, and not bulked with other sorts of bark.

We must defer till our next circular the discussion of the requirements of the manufacturers as affecting the preparation of bark for market. —*Ceylon Observer*.

SERICULTURE.

VEGETABLE SILK.

THE possibility of obtaining vegetable silk is based upon the observation first made by Mulder that silk is soluble in certain liquids without being decomposed by them. While, for instance, cellulose is dissolved and at the same time destroyed by concentrated sulphuric acid, fibroin, the real substance of silk, dissolves in muriatic acid, in a solution of the oxide of copper in glycerine, &c., just as sugar dissolves in water, and though, of course, disorganised (*i.e.*, its structure destroyed), it can be reprecipitated as fibroin from all these solutions. In this re-precipitated state it appears, after being washed and dried, as a soft amorphous powder of a silky lustre, and capable of taking up certain dyes from their solutions without the aid of a mordant.

In order to make use of these facts in cotton dyeing, by precipitating the above substance on the fibre of cotton according to well-known principles A. Muller and E. Sopp obtained, in 1871, French, Belgian, and English patents for the production of a mordant from silk waste, by means of which greater brightness is communicated to vegetable fibres, and they are rendered capable of taking up dyes in the same manner as silk.

This process, in consequence of various technical defects, has fallen short of the great expectations entertained, and has remained dormant. The patentees never intended in this manner to convert cotton into silk, but remained, as may be seen from the title of the patent, within much more moderate limits.

Whether other chemists who have taken up the first idea and have enlarged it into the "conversion of vegetable fibre into silk," have been more fortunate, we are unable to decide. The matter is, however, worth a close examination.

TOBACCO.

A VERY general opinion prevails that two or three crops of tobacco are sufficient to ruin the best land. No more erroneous opinion could exist. Tobacco extracts, principally the nitre from the soil, which enters very slightly into the nourishment of any other of our products. The drain on this element can be counteracted in two ways; first, by sowing rye on the land immediately after cutting the tobacco, and ploughing it under the next May; rye is not only the most fertilizing of all the cereals, but contains more nitre than any other; second, by cutting up the tobacco stalks, which themselves contain a large proportion of nitre, into pieces three or four inches long, scattering them back on the land and ploughing them under with the rye. Land treated in this manner is capable of producing as many consecutive crops of tobacco as of corn without material injury to the soil. Three acres of land so treated have produced the fourth consecutive crop, which compares favorably in texture, weight, and color with the remainder of the crop grown on virgin soil; and land so treated for three years produced corn in 1879 as heavy and well matured as that grown on the same quality of land lying immediately adjacent and which has produced only its second crop from the sod. Probably one cause of the widespread opinion as to the injury to the soil resulting from the culture of tobacco lies in the fact that a large proportion of the tobacco cultivated in Kentucky and elsewere is grown on steep hill-sides, the inevitable washing away of which, consequent upon cultivation, suggests a ready reason for the rapid depreciation of the land, outside of the exhaustion produced by the crop. Tobacco is undoubtedly an exhaustive crop, but with a careful and judicious system of farming it can be successfully and profitably grown on blue-grass lands with as little damage to the soil as that resulting from the culture of hemp or corn.

TOBACCO cultivation is now pursued with unusual energy in the country. We believe that, at this season, there are more lands under tobacco than on any former period. Extensive tracts of waste lands have been reclaimed for this purpose at great cost. The demand for compost manure is very great and the price per cart-load generally reaches Rs. 2·25 we are told. It would be well

if local cultivators turn their attention to imported manures, many of which are said to possess properties that will be of much value for the weed.—*Jaffna Patriot.*

TOBACCO.—The United States produces annually between 400,000,000 and 500,000,000 pounds of tobacco. The world's annual product is estimated at from 1,500,000,000 to 2,000,000,000, In the United States, fully 50,000 persons are employed in the manufacture of tobacco, earning £2,800,000 in wages, and turning out a product worth £14,400,000. Tobacco ranks sixth on the list of American exports, and last year the United States sent abroad about £10,000,000 worth. Germany is her best customer, but Great Britain follows closely.

HOW TO GROW AND CULTIVATE WHITE BURLEY TOBACCO.

PLANT-BEDS.

To be successful in raising a crop of tobacco depends entirely upon the first step taken in that direction. Secure plenty of plants and have them early. Select for plant-beds a fine soil (south or south-east exposure—new and slightly elevated), and ground holding sufficient moisture so as not to dry out during the day; burn your beds sufficient to kill all the seed of grass or weeds; then you are ready to dig up your bed. Dig in the ashes well, then rake and pulverize every clod; be sure and take out all roots, rocks, and whatever other obstructions may be found in the bed. Sow your seed any time from the first of February until the last of March. Sow a bed for every acre you intend planting is a good rule to go by. Sow about two large tablespoonfuls to the hundred square feet. Then one of the most important parts is securing the plants, and do not fail to do it by brushing your beds heavily with a green brush. The seed should be mixed with ashes or corn meal before sowing, so as to prevent getting them too thick.

SOIL, &c.

The soil best adapted to the white burley tobacco is generally given up to be of a limestone nature. The best and finest tobacco that comes from the cutting district is grown on new land, first and second crops, and in some cases a good crop is raised the third year, but that is running the ground too hard. All our fancy cutting tobacco is raised on such land, and as a general thing it is underlaid with limestone, although we raise a really nice article on old land. It should be the aim of every tobacco grower to go for quality.

PLOUGHING AND CULTIVATING.

Land intended for tobacco should be ploughed in the winter, if possible, and ploughed deep, if you expect a crop. In the spring the ground should be turned with a double-shovel plough and harrowed and rolled, if rough and cloddy. The more you cultivate your land before you get your crop out, the less work it will take to tend it after it is set. After you have it planted, keep the plough and hoe going constantly, and plough just as deep as possible. The best plough for that purpose is a double-shovel plough, shovels not wider than three inches and full ten inches long. The more work you give your tobacco, the better body it will have.

TOPPING, SUCKERING, CUTTING.

Now comes another important point in the growth of the crop, and that is topping. Don't top to more than 14 to 16 leaves at the farthest, your top leaves will all fill out well and mature, and be as large as any on the stalk. As to cutting, don't cut until ripe, which is about four weeks after topping. Keep all suckers off, to concentrate the strength of the plant in the leaves. Suckering tobacco is very tiresome, and is the most laborious work that is connected with the crop. Worms and suckers at this period in the crop demand the planters' entire attention until it is matured and ready for the knife, cutting is now to begin; a good hand will cut from 500 to 800 sticks a day, and some extra hands 1,000 to 1,200. Place from eight to ten stalks on a stick; you will have to be governed by size of plants.

HANGING AND STRIPPING.

In hanging in the barn, the sticks may be hung about eight inches apart, if dry and well wilted. Never take tobacco in the barn if wet with dew or rain, as you are likely to have it house-burned. Never use fire in curing white burley tobacco, as the smoke renders it useless for cutting purposes; but keep the barn open, so that the air can circulate freely. When your tobacco is sufficiently cured to strip, you should be careful in keeping each sort by itself. First, keep all the chaffy trash leaves together, then your bright lugs; next comes bright leaf, which is about the centre of the stalk, and sometimes all on the stalk is bright after the lugs are off. Be sure and keep each color and each length together by itself.

BULKING.

Having your crop all stripped, it is now ready for bulking. Great care should be exercised in having the case right, as too much casing will cause your tobacco to funk. Heavy bodied tobacco will stand more casing than a fancy article will to get in proper condition for bulking. It should dry out thoroughly after stripping and then, as the leaf comes in case before the stem, it should be just moist enough, so as not to break under your knees as you bulk it. The stems may be dry enough to break, but that will not damage the tobacco if the leaf has sufficient moisture to keep it from breaking.

PACKING AND PRIZING.

Next comes prizing in hogsheads, preparatory to shipping. This is not a very great task, but a great many make it so. There is but one way in which tobacco should be put in the hogshead, and that is, every kind you have should be packed in a hogshead by itself. Prize not over 1,000 to 1,100 net pounds to the hogshead. Don't mix different kinds together; if you do, you are sure to get the worse of the draw, and your tobacco will sell for what the lowest grade in your sample is worth; therefore, you lose all your good tobacco simply because a few hands of trash or some other worthless article is in your sample.—*Journal of Agriculture.*

CONTENTS.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces; that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

CORRESPONDENCE.

COWDUNG.

TO THE EDITOR.

SIR,—Will you kindly tell me whether cowdung if exposed to the sun for a month or six weeks will deteriorate? I was very much obliged to you for your note regarding the "keeping of tea in tin boxes.'

TRAVANCORE TEA PLANTER.

CATTLE-BOX MANURE.

TO THE EDITOR.

SIR,—In your issue of the 10th instant, I notice an interesting article on the results of experiments on the different kinds of manures tested by Mr. Harman at the Government Experimental Farm at Bangalore, and I would be extremely obliged by your kindly explaining to me what is meant by "Cattle-box manure."

KENNETH DONALD.

Our correspondent will find his query answered elsewhere.—ED., *I. A.*

RHEA FIBRE MACHINE.

TO THE EDITOR.

SIR,—Please allow me to explain the exact state of things relative to my machine and process, as I think the notice you kindly gave may produce an unfavourable impression.

I must state that, practically and commercially, I have most effectually got rid of the difficulty arising from the glutinous matters of the plant, by first boiling the stems. In this process at least three-fourths of the gum is set free, and the vegetable albumen becomes fixed and ceases to be an impediment to the removal of the cortex. As to the wood—that has never been a cause of difficulty, and is always most easily removed. In my case at present, in consequence of the stunted condition of the Rhea grown at the Botanical Gardens, Howrah, no wood—so to speak—was formed, and few of the stems exceeded 1 foot 6 inches in length, and certainly none thicker than a pipe stem. This failure of the crop must be taken into account, but the real and principal cause of the result not having been more definite was one entirely beyond my control. When the last day's experiment was performed, I was struck with the fact that the oscillation of the upper rollers in the forward direction of the drum's revolution did not move at all—in fine their action was *nil* in this direction. I investigated the cause of this defect, and soon found that a *pinion* wheel of only 13 teeth, was occupying the place of one which has 25 teeth, these wheels being connected directly with the crank shaft of the machine. Of course the change of these wheels would give the machine four times the executive power, and produce corresponding results. The error arose from the workman of the makers having in the hurry of packing put on the shaft the wrong wheel. I hate excuses, still I love the truth, and these being the facts, it would be extremely unjust to condemn the machine because of the untoward accidents of the condition of the 12 maunds of stunted rhea and the mistake in the wheels. These are trifles light as air; but, to the ignorant, proofs against the machine and process, which cannot be allowed to remain unnoticed by me. My experiments in spite of the difficulties in the rhea and the lame state of the machine have been a great success and demonstrated and corroborated two most important facts—1st, that the boiling process does not in the least degree deteriorate the fibre; 2nd, that the bark is easily removed, and the fibre is practically and commercially clean.

If there remain a few specks of bark, these disappear at once on the alkaline boiling in Europe for the removal of the resinous substance of the plant. I have proved that the Rhea imported into England from China contains full 35 to 38 per cent. of resin and other extractive matters; still this commands from £40 to £50 the ton. It is the limited supply from China which prevents the more extensive use of this, the most valuable of all fibres. The Chinese prepare it by hand; one Chinaman can decorticate from 2lb. to 2½lb. per day, leaving 38 per cent. of extractive matters. With my machine, which is now to be placed at Messrs. Gladstone, Wyllie & Co's Jute Mill, Garden Reach, on the coming season when the Rhea crop will be more propitious, I will demonstrate that this machine will operate most effectually on 1¼ ton of Rhea stems per hour and extract from the same 210lb of clean marketable fibre worth at a minimum £35 the ton at a total cost of all and every condition, including the cultivation of the Rhea at one pound the ton, covering labour, fuel, wear-and-tear of machinery, interest on capital at £10 per ton, leaving a clear profit of £25 per ton. I, will shortly leave for England, and if I do not return, I will elect a competent representative.

ROBERT COLLYER, M.D.

TEAK SAPLINGS.

TO THE EDITOR.

SIR,—In continuation of my letter published in your issue of October last, I send some further particulars of teak plantations in this district. In November 1878, I put down 70 plants, averaging 9in. in height, of teak which had germinated spontaneously from seed dropped from the parent trees given in alluvial soil. The soil of my plantation is the red ferruginous clay found in the proximity of laterite formations such as that of Tanjore. On taking the measurements of my plants at the end of 12 months, I found their average height to be 6 ft. 9in. ! I may mention that they were carefully watered and pruned during their growth.

CAPTAIN, R. E.

Tanjore, 17th April 1880.

SOAKED *vs.* BOILED GRAM.

TO THE EDITOR.

SIR,—Can any of your numerous readers inform me whether there is any truth in the tradition which the natives of this district have, to the effect that the use of soaked gram (*Dolichos uniflorus*), instead of boiled, for feeding draught and milch cattle induces in the latter a failure of eyesight, after this food has been continued for a couple of months or so? It appears from what the natives say that cattle thus fed cannot see after sunset, and they assert that all the Government Commissariat cattle are in this peculiar condition in consequence.

R. R. E. BROCKMAN,
CAPTAIN, R. E.

Tanjore, 21st April 1880.

SERICULTURE.

To the Editor of the Ceylon Observer.

SIR,—With reference to Mr. Horsfall's letter to you on this subject, published in your issue of 5th instant, the scheme proposed seems rather impracticable. I presume that the insects referred to are the larvæ of the oleander hawk moth, from the description given of their ravages, but this insect does not belong to the Bombycidæ. Mr. Horsfall tells us, though, that he has recently seen some cocoons collected from the branches of cinchona trees, so that it is evident that, unless these were produced under artificial conditions, they were not cocoons formed by the ordinary larvæ so common especially on succirubra.

I am aware that there are other species of larvæ that feed on cinchona, having met with two kinds myself, but I do not remember to have anywhere seen any whose silk would prove remunerative. The common caterpillar, *Deilephila nerii*, constructs its cocoon in the earth, small particles of which are mixed up with the threads, but these are so interlaced that I question if winding them is possible.

But, even if the cocoons shown to Mr. Horsfall were produced by other insects, and their silk was worth cultivation, I still fail to see why our cinchonas should be sacrificed for the sake of a new industry, the permanence of which is doubtful and the profit uncertain. Mr. Horsfall says that the prunings alone would supply a large part of the required food (the worms feeding on other plants besides cinchonas), but he is apparently not aware that it is absolutely necessary to feed silkworms on one kind of food only, from the times of hatching until they spin their cocoons. I have hitherto believed that the quality of cinchona bark depended in no small degree on the minimising of light, and that the most moderate pruning possible was desirable in order to secure the secretion of alkaloids. But Mr. Horsfall tells us that this secretion is known to be stimulated by every measure that tends to check too great luxuriance, so that I am apparently mistaken. I am, however, rather doubtful if our trees are likely to suffer much from this cause, for we have been told by Mr. Hughes that Ceylon soils are naturally poor, and few of us at present manure our cinchonas.

But admitting I am wrong on all these points, there is one objection to the proposed use of prunings, which seems a serious one. Cinchona branches, in order to be kept fresh, must have their stems immersed in wet sand, and must be frequently changed. The worms will not readily leave their position on the stalks, so that it would be necessary to leave some of the old food with each of them when giving a fresh supply, and I think that this accumulation of *debris* and the continual damp occasioned by the wet sand would in very little time engender disease.—Yours faithfully,

SCRUTATOR.

April 8, 1880.

[The most considerable and successful experiment in sericulture made in Ceylon we suppose, was by Mr. Bury on Golconda estate, Haputale; but the result was not very encouraging. Thunderstorms are very injurious to the health and even lives of silkworms, and in this respect Ceylon is at a disadvantage. We do not know if the same objection would apply to the cinchona caterpillar, and the experiment suggested by Mr. Horsfall is well worthy of a trial at least.—ED., *C. O.*

CINCHONA SEED.

To the Editor of the Ceylon Observer.

SIR,—Now that the cultivation of cinchona is extending so rapidly in Ceylon, there must, I presume, necessarily follow a desire amongst cultivators to secure seed of the more valuable kinds. This appears to be a most difficult matter for private individuals to accomplish, and you would be conferring a great benefit on the planters of Ceylon by urging upon Government the great and pressing necessity of establishing Government cinchona gardens if on ever so small a scale. The Indian Government is very far ahead of us in this respect, and is, I believe, in a position to supply seed of the more valuable kinds of cinchona to the planters in the Neilgherries, Sikkim, &c., and the seed so supplied can, I understand, be relied on as genuine and valuable. One constantly sees advertisements in your paper of guaranteed Ledgeriana plants and seed, but one fears to purchase at the prices asked, for fear of not securing the real article. Could you or any of your numerous readers enlighten me as to the supply of Ledgeriana seed available from Java at the present time, and whether statistics as to quantity of seed which has been sent out during the past two or three years from the Government gardens, Java, are procurable. Some of your readers may be in direct communication with Java, and if so, would greatly benefit their brother planters with a little information upon the subject. It would be a serious matter to expend a large sum of money upon seed and plants which might prove worthless, and at present we are most lamentably

IN THE DARK.

March 22, 1880.

FIRE AND FIRE LINES.

To the Editor of the Pioneer.

SIR,—Having seen a letter in your paper suggesting that, perhaps, fires in forests were beneficial than otherwise, and having also read your Review on the Forest Reports, I waited for many days to see if no one more competent than myself would answer them. No one having done so, I have ventured to send you a few remarks on both these letters. Knowing how hard theory is to prove, I will do my best to stick to facts only. Your correspondent (I, having mislaid the number of the *Pioneer* in question, cannot give his signature) questions whether fires by manuring the ground with ashes are not more good than harm to the forest. I will try to prove to him that fires in forests are second to nothing in the damage they do to the trees. Even in England fires are strictly prohibited, and then although trees are almost, so to say, gardened. I never heard of ashes being applied as a manure to them, although largely used for carrots and other crops. I was reared up on the borders of the Woolmer Forest, and can well remember the general features of the place. Many herds of three-quarters wild ponies, villagers' cows and geese, and small lots of pigs and sheep grazed in the forest there, and often fires were lighted and, if the season

was a dry one, burnt for days. Since then the Government has closed the forest. To the astonishment of many, without seed being sown, it now grows large patches of fine pine or fir timber, nothing having been done to promote their growth but protection from fire and grazing. I must state that there always were a few clumps of old fir trees about. I saw the forest last year many times, and was astonished at the change. Not far from the same spot is Wiltey Common, where the same thing has happened exactly. At Liss, on the road from Liphook to Greatley, and near the rifle range in the forest, are the most remarkable changes in my eyes. Near the rifle range a fire had killed many hundreds of fine young firs. If protection from fire is so beneficial in a damp climate like that of Hampshire and Surrey, how much more must it be so under the burning of an Indian sun in April? The effects of fires may be briefly described as killing all vegetation that is small enough to be killed, or burning all that is dry enough to blaze. After a fire has passed over the ground, the surface is left bare; the following rainy season beats the surface very hard; the following dry season bakes it. Surely that is hardly the way your correspondent would prepare his garden seed-beds. On the other hand, protect that forest from fire, the leaves and grass rot on the ground, making year by year a thicker layer of leaf mould. The rains fall on the leaf mould; it acts as a sponge, and prevents the water running into the rivers as fast as it falls, which it certainly does off the burnt surface. The only fact I can imagine as being brought against the protection from fires, are insects; but take insects in the lump (I mean what outsiders usually call insects, and not the naturalist definition of them), they are cultivators very often, ants especially. Think of the tons and tons of soil they cause to change places; but allowing that insects do increase to an enormous extent, surely it is better to be able to say that the forests are infested by insects, than to say there is not food enough for caterpillars to live on; but the rule is that, when any form of insect increases, another that feeds on their bodies does likewise, so I do not fear any stoppage of forestry from insect life. In your Review of the Forest Reports, you say, *the system seems to be (alluding to fire conservancy, &c.) to cut diagonally what are called fire-paths some fifteen feet broad.* Further on, after Mr. Campbell's fruitless attempt is described, you say. *It may be imagined how useless a fire-path of fifteen feet wide must be to stop such a fire as this*; and I have no doubt you are perfectly right, as there are few places where a fifteen-feet path *alone* would stop a fire; but you have been misled somehow, at least as regards the North-Western Provinces. You are quite right in calling the path a fire-path, but you have forgotten the *fire line*. The grass is cut on either side of a path, say from twenty to ninety feet, according to height of the grass, making a total of fifty-five feet to 205 feet for the width of *fire line*. The fire-path is included in this. The object of the path is to prevent creeping fires, and it has to be kept strictly clean of grass, leaves, or anything that will burn, and it is sufficiently wide to stop the creeping fire when it gets into the stubble of the cut grass. The fire line is the thing that stops the raging fire (or is meant to). I would also point out that what is sauce for the goose is not sauce for the gander; I mean that a 400-feet fire line might be required in one bit of grass, and then fail to stop a fire, perhaps, if the wind was blowing a real gale; whereas five feet clear and clean would do it, perhaps, not a quarter of a mile further on the same line. For instance, on the top of a sharp ridge, the fire can be stopped by a small six-feet path; in the bottom of a steep *khud*, with well-wooded sides, twenty feet is ample in many cases; but on a broad *maidan*, where the grass is high, with the wind blowing over the open, unbroken by trees, then may the forester shake his head, and say, "Oh, cruel fate!" The proper thing to do with *maidan*, of grass is to fire them in November and December, as then the high grass is burnt into patches. The width of fire lines must be determined by observation and experience; as, if too wide, money has been thrown away. There is no doubt that, as the young stuff grows up, the cost of protecting it will become less.

O. GREIG.

THE CULTIVATION OF TREES.

(FROM A CORRESPONDENT.)

A CORRESPONDENT of the *Indian Agriculturist* wrote to that paper early last year, wanting to know whether the girdling of apple-trees would cause them to yield in greater perfection, but up to the present time there has not been a single reply in that paper for, or against, such a process. The question, however, was answered privately, so that no time should be lost in preventing the death-warrant being issued against the trees, this being a process that all trees that are to be felled for timber undergo, in the first instance, not so much as a distinguishing mark, but to dry them before they are cut down; hence, when cinchona trees are barked, there is still a long surface of the bark allowed to remain intact, while by mossing and other methods, the parts stripped once more regain what they were deprived of.

All fruit trees with gum or milk in the bark may be subjected to the following process. When the young fruit has shown its appearance, cut notches in the bark. If of 24 inches in circumference, run one line of chalk-mark round the body, at, say, 4 feet from the ground, then run another chalk-mark round it at a distance of one foot above; or at least that is just as I did to one solitary mango tree that was in bearing for the first time. I had many others, some that were in bearing for several years, and one that was in its first season. From this last I did not get a single fruit, all fell off prematurely; the other trees also lost largely in the same way, but on the wounded tree, the fruit exceeded in size that of every other tree in the garden, and while fruit was falling plentifully by the force of the wind from day to day from other trees, none fell from this. But I saw that they had become too heavy to stand any squall, so I got all the straw-cases of bottles that I could, into which I introduced the fruit, tying up the mouth of the straw-cases with dried plantain stalls, taking the weight of the fruit from off its stalk, and transferring it to the branch by the same piece of string; then to prevent the case from dangling and being caught and torn by the other branches, I tied the other end to the same branch with the same kind of plantain stalk, thereby securing the straw case to the branch from end to end. For want of more straw cases I got long straw, tied a good handful up at one end, settling the fruit carefully within, and securing all in the first instance. The long grass being cut, I got the dried stalk of the plantain tree, tied the ends of the stalk together, and enveloped the fruit in it, and secured it in the same way. That same night a heavy squall of wind and rain came on. All the trees in the garden lost nearly all their fruit, while this one tree did not lose a single one, though there was not the least shelter of any kind near it. In about a week after they were getting ripe, I measured thirty-two of them; they gave ten inches and five-eighths in length and ten and-a-half in circumference. In fact they were the largest mangoes in the garden, and all who saw them, said they never saw anything like them in that place. Mr. Strettell in his journal states that while on his journey to find and compute the area occupied by the India-rubber tree in Burmah, the Chinese, on the frontier close to Bamoo, wounded their pumalow trees in a similar way, for a like reason, the sap that has risen to its full extent being retarded from running down, and consequently remaining to supply the fruit with nourishment. But the custom is a wide-spread one, as we may learn from that passage in "Sam Slick" on the taming of the shrew, where he tells us "Father used to say—a woman, a dog, a walnut tree, the more you lick em the better they be." So from this it is evident that the walnut tree must have yielded a larger quantity of nuts, by this licking, *i.e.*, the bark of the tree is beat en with a stick, or back of a chopper. When mangoes are blown down by squalls, they are in general allowed to be a total loss; this ought not to be so, because by carefully removing the rind, and slicing the fleshy part thin, and drying them carefully, and then pounding in a morter, and passing the dry powder through a cloth, then putting the powder into mustard bottles, putting them out in the sun occasionally to keep the powder dry, the powder will be found to give curries a far better taste and flavour than tamarind, this latter article being in general exposed, to dust and flies from day to day, in the bazaars.

I will now give a few lines about the jack tree, and close for this time. A Bangalore correspondent of the *Indian Agriculturist* shows the advantages of planting the jack seed in the exact spot in which it is intended the tree should spring up and grow permanently, the only drawback to this being that the gardeners are "likely to dig the seeds up and either roast or boil and eat them." To those who would wish to plant jack trees, I would offer the following advice. In the first instance make choice of the largest and best fruit you can get; let it remain on the tree till it is so ripe that you can press your finger in. If the seeds have sent out their roots, then take all out. Place the seeds in a shallow basket of cowdung for a couple of days: by this time they will be so impregnated with the fumes of the dung, that rats, or gardener will not have any thing to do with either nibbling or eating them. It is only the old well-grown trees that bear fruit or the root underground; the trees begin bearing fruit in the main limbs, then on the body or butt, and last of all on the root below, the ground begins to crack; then the ground is dug about and loosened to give room for the fruit to expand. The fruit is not removed until it sends out a ripe, sweet smell.* This bearing on the root is not confined to any particular variety; all bear alike on arrival of the tree to its full age. Can any of your readers tell how this fruit came to be named "Jack?" The first place that Europeans landed at in India, was the Western or Malabar Coast, say Calicut. On inquiring the name of the fruit from the natives, they were answered "chuckray," this being the Malayalam name for Jack." The Portuguese improved it into "Jaca," and the English into "Jack." I have not seen any one in India extract a dye from the wood. In Burmah even the sawdust and chips are carefully gathered up, and all the clothing of the phoonghees, or priests are dyed yellow from the liquor of this wood. It was in a similar way that the gold coin of Madras was called "pagoda." During a Hindoo festival a goddess was coming out on men's shoulders, the wondering Europeans wanted to know what it was, to which the natives replied by giving the name of the goddess as "Bagotheeummal." This led to the gold coin with the temple on it being called "pagoda!" We have all heard of the pagoda tree; the present generation only know it, and its fruit, by tradition.—*Madras Mail*.

OBSERVER.

NOTES FROM ATTOCK.

ATTOCK and neighbourhood are very bare of trees; the entire country was once well covered with arborescent vegetation, of which it has in the course of centuries been denuded. The cultivatable area has in consequence largely decreased, and the surface of the country having had nearly all its humus washed into torrents, presents generally a wild and desolate appearance. In the immediate neighbourhood of villages and within the influence of short lengths of irrigation channels, agricultural operations can be carried on with advantage to the villagers, but all outside that is very unproductive, and is but slightly cultivated, and even then, only after considerable time of fallowing, even the limestone table lands are uncultivatable in places.

The barley is ripe, corn is ripening; as soon as the former is cut, the ground will be prepared for joar. The ber (*Zizyphus*), loquat fig and mulberry are now fruiting: the pomegranate; bead (vern. bakáin) smelling like lilac, shisham, lime, orange, and wild caper, are now in flower. Roses in abundance; a few larkspurs, geraniums, maiden hair fern; of vegetables there are only onions, lettuces, radishes. Strawberries are in flower. The plane poplar came into leaf at the beginning of March. among the wild shrubs the ak (*calotropis*); verma (Rhazya) pleasant scent; hermal (one of the Rutaceæ); and some others are in flower.

Village arborescent plantations would be of great service to this part of the Punjab.

Kúnd, April 4, 1880.

The Indian Agriculturist.

CALCUTTA, MAY 1st, 1880.

ON CLEANING GRAIN.

WE observe with satisfaction that attention is being paid to the important subject of cleaning wheat. In no other country in the world would wheat be exported in an unclean condition, necessitating the paying of freight on dust and foreign matter. This averages from 3 to 10 per cent., five being an average perhaps not on the side of excess. It does seem strange that this has not been attended to long ago. The local importers and exporters have been steadily paying railway freight and steamer charge on five maunds of foreign matter in every hundred, for no earthly reason than that they have been too indolent or indifferent as to the cleaning of it. It has also been said that they have had to pay the price of wheat for this five per cent. of dirt, but this is not correct, as grain and seeds are purchased in Calcutta under a "refraction" clause, which virtually removes the charge for this useless excess. We may assume, therefore, that if grain and seeds were absolutely clean and unmixed, or as nearly so as we can reasonably expect, the price would be proportionately increased. Hence the present loss to the merchant is in freight. There is, however, another loss which the merchant has to bear indirectly, but which falls directly on the cultivator. Indian grain—wheat in particular—has acquired a bad name from this impurity, and hence a much lower all round value is put on it at home. And it may safely be assumed that the merchants at home, whose valuations practically control the market, take care to err on the safe side for themselves, in thus depreciating the market value of Indian grain. Two difficulties lie in the way of our sending clean grain, and they are, the present mode of threshing, and the expense of introducing an improved method. We might perhaps add as a third, the habit of growing two crops simultaneously. This does not so much account for dirt as for the introduction of foreign grains. The cultivator sows together crops which will ripen perhaps three weeks apart; when the first is ripe, it is gathered by cutting the ears only, the straw being allowed to stand till the other crop is ready. It, however, happens that along with the first crop handfuls of the second and unripe grain are also cut; or, if the first crop has not been all removed, the remnant is cut along with the second. From either cause the two get irretrievably mixed up, to the commercial deterioration of both. The proper kind of threshing, winnowing, and separating machinery might to a large extent remedy this, but here the great pecuniary difficulty presents itself. If we wish to clean our grain properly we must first of all introduce improved threshing machinery, and the initial difficulty here is not, as might be supposed, the native conservative objection to anything new, for with all his faults, the cultivator is ever ready to adopt an improvement provided the success be certain, and the cost not more than the cost of his own method. But, so far as experiments have gone, the latter condition cannot be realised, as the native system is beyond doubt the cheaper. We are convinced, however, that the ultimate results of the use of improved threshing machinery would show that it was cheaper in the end than the native process, and our great difficulty will be to convince the cultivator of this.

For instance, the advantages of improved threshing, winnowing, and separating are thus shown, as compared with the method in use. It has been found by careful experiments that treading out the grain leaves from 10 to 15 per cent. unseparated from the ear, while threshing by machinery separates all; that steam threshing costs sixteen pies per bushel as against three pies per bushel if done by cattle treading, but that the outturn is worth two annas per bushel more from being cleared of foreign matter and dirt. Supposing the grain as now produced be worth to the cultivator Rs. 2 per maund, this is equal to Re. 1-7-5 per bushel. The account-current then would be as follows. Say the experiment was tried on a quantity of grain estimated to produce 100 bushels :—

By bullocks :—				
85 bushels grain in marketable condition ...	@ 1 7 5	124	6	5
10 bushels left in straw ...			?	
5 „ „ dirt ...			?	
		124	6	5
Less cost of cleaning 100 bushels ...	@ 3 ps.	1	9	0
	Nett value Rs.	122	13	5
By steam power—				
95 bushels grain in marketable condition ...	@ 1 9 5	150	14	7
5 „ dirt ...			?	
		150	14	7
Less cost of cleaning 100 bushels ...	@ 0 1 4	8	5	4
	Rs.	142	9	3
	Balance in favor of Rs.	19	11	10

If it be urged that the resultant straw by the machine process will not be so valuable as that by the other, on account of its not containing the ten bushels of grain, we reply that it will be more valuable, and for this reason: the straw trodden by the cattle is so cut up by the irregularity of the pressure exerted upon it, that it will not keep any length of time, while that chopped in the machine, is done at one operation, and is not bruised unnecessarily, while it is clean and unmixed with dirt, and hence of a higher value as a cattle-food. What, then, we may ask, is to be done with the view of improving the condition of our grain? Granting machine-cleaned grain to be the best and ultimately the cheapest, how are we to set about the introduction of machinery? Two methods present themselves—the introduction of powerful steam machines, and the providing of smaller ones, to be driven by hand or bullock power. For many reasons the former would be preferable. The work would be better done and at smaller cost than by the smaller machines, but there is one objection to their use in India, which must be considered fatal, and that is, the want of roads for moving them from place to place; our village roads not to speak of main roads, make this impracticable. Consequently we must revert to smaller sized machines, and doubtless these could be provided at a reasonable rate, one for each village or group of villages, the cost of purchase and keeping up being chargeable *pro rata*, the rate being based on the quantities

cleaned by each cultivator. In connection with the estimated cost of threshing and cleaning grain by the present cattle treading process, nothing has been charged for the labour of the cattle or of the men driving them, the estimated cost being principally made up of the hire of women for winnowing purposes, and the purchase of *soops* and other implements adapted to this mode of operation. The reason of this is that a cultivator does not think of debiting the cost of his own cattle's work, which is an error. When a cultivator has to hire, as is sometimes the case, if the weather is threatening, the cost of threshing and winnowing is raised to nine pies per bushel instead of three.

AGRICULTURE, N.-W.P.

THE memorandum by Mr. Buck on the measures proposed for adoption on the Awa estate under the Court of Wards is a very carefully compiled document. We may from time to time feel called upon to dissent from the action of the Department of Agriculture and Commerce, N.-W. P., but on this occasion we have little but praise for the intelligence displayed in the suggestions made, and this not so much on account of the agricultural value of the suggestions themselves, as for the evidence scattered over the memorandum, leading to the conclusion that the proposal has been carefully arrived at, and that due regard has been shewn all through it to the prejudices of the cultivator, so far as may be done without detriment to the success of the experiment. This is of more importance than many will admit, but it is undoubtedly true that if we wish the cultivator to leave his old beaten tracks, and follow our leading, we must not begin by shocking his prejudices by changes too abrupt, however valuable they may intrinsically be. It is hardly worth while to take the trouble of proving our right to make these experiments on the properties entrusted to our care under the Court of Wards. Notwithstanding the objection raised to the justice of our making any experiments in these estates, we conceive we are not only justified in doing what we feel convinced will prove of ultimate advantage to them, but that we are guilty of dereliction of duty if we fail to do so. We are clearly bound to do for them what we or any wise, intelligent and liberal landlord would do for his own property, if he had the available funds. Mr. Buck disposes of this objection by two propositions. He says—"Government ought, in my opinion, to do nothing that it is not prepared to advise or perhaps require other land-owners to do;" and again, speaking of the proposed experiments in the Awa case, he says—"none are to be tried which have not elsewhere proved improvements, and which have not, therefore, a *primâ facie* prospect of success." These seem to us to dispose of the objection. A sytematic attempt is to be made to get rid of *reh*, and it is to be utilised as far as may be in glass-making. On the subject of wells, it is proposed to spend ten thousand rupees, Awa being a district where canal water is not to be depended on. The wells are all to be *pucca*, and this money therefore cannot fail to be well spent, if ordinary care be exercised over the work. In this connection might it not be advisable to try tube wells. They are found to give satisfaction, and where sunk to the depth of 100 to 150 feet in India, usually become practically artesian wells, from which the water runs spontaneously. Even at the cost of a little more expenditure in boring, this advantage is worth trying for, as the cost of drawing the water when wanted is always a heavy drain on the cultivator, and to do this, he is frequently compelled to withdraw his cattle from other field operations. The question of the improvement of cattle is next taken up, and here it is thought that legislation will be necessary, and on this point we are perfectly at one with Mr. Buck. What will be the use of introducing, say, half-a-dozen superior bulls into a district, if there also remain with the general herds dozens of common country bulls; on this point it seems clear that some wise legislation will have to be passed. There is another difficulty. It has long been a custom for wealthy natives to permit Brahmini bulls to roam at large among the village cattle. This was originally done from religious motives, and is probably so done still; but the objection to it is, that in many cases these very bulls are the very last that a prudent stock-raiser would think of breeding from. One point besides will have to be attended to. If the stock be improved in quality, better arrangements will have to be made as to feeding, as the present mode of feeding will not support a superior breed of cattle. The planting of timber both for fruit and firewood purposes has not been lost sight of, and this we look on as perhaps the most promising of all the suggestions made. Given the country well covered with reserves of timber, our periodical famines and scares will speedily disappear. The difficulty in the way is how to set about this. We are not among the number who think that the Forest Department should attend to this. However we will not discuss this vast subject at present. On the subject of the plough, we are not quite at one with Mr. Buck, as we think it a mistake to endeavour to introduce a plough on an English model however good, the double handles being we are afraid a fatal objection. The improvement of crops by a careful selection of seed is next discussed, and the pedigree selection system advocated is no doubt the best, but to be successful, we fear its adoption must be begun by the Government in its model farms and agricultural schools. Doubtless a liberal system of agricultural shows and good prizes for the best set of heads might do something, but if pedigree grain is to be raised in any useful quantity, it will have to be done by intelligent European agency. Besides the more ordinary agricultural operations, we find that attention is also being directed to the introduction at Awa of improved machinery of various sorts, so that Awa, if these schemes get a fair trial, ought to be a model estate. The new sugar mill of Messrs. Thomson and Mylne, is highly recommended for introduction. It seems to be the opinion of Messrs. Buck and Benson that the "bunnia" system might be made use of in the introduction of improved seed, &c. Here we differ, as we cannot conceive the bunnia being of any use except to himself; his whole instincts lead him to screw all he can out of the cultivator, and we cannot imagine him interesting himself in improvements. The introduction of new staples is taken up with caution, and this is highly commendable, as the inclination is to run to extremes in this direction. Their planting and sowing have not been overlooked, but as Mr. Buck says —"In this, as in all tentative experiments, great care should be taken to test the new system by comparison with the old." This caution speaks well for the success of the experiments. On the subject of their sowing, we presume it has now passed the experimental stage, and the system may be considered a success. Mr. Hume's remarks on those proposals will be read with interest by all who have studied the subject of Indian agriculture. They are characterised by sound sense, and are therefore more valuable than the quasi-official utterances of members of the Government who have not studied the subject.

EDITORIAL NOTES.

DR. COLLYER has recently been trying experiments, with the view of showing the capabilities of his new rhea machine, and we are sorry that a more definite result has not been obtained. It is perfectly true that the machine crushes out the wood without injuring the fibre, which remains intact the full length of the wood; but the great difficulty has not been got over, and that is the removing of the glutinous substance which is peculiar to this fibre, and which stands in the way of its being thoroughly stripped by *any* mechanical process. We believe that this machine of Dr. Collyer's will do the mechanical part of the work thoroughly well; but we do not see how it is to be utilised completely until the other difficulty is got over. Experiments were tried with raw wood and with boiled, and the latter undoubtedly gave the better result, shewing doubtless that the boiling tended to remove a portion of the mucilaginous secretion of the plant. So far as this particular trial is concerned, we may mention that the rhea plants supplied to the Doctor were very far from good, being only about two and-a-half feet long and composed almost entirely of bark and pith: ripe wood was entirely absent. In consequence of this, the machine of course had not a fair trial, as the rollers were formed to crush wood and not soft pith. It is marvellous that such a delay has occurred in receiving the award from London relating to the trials of the several machines at Saharunpore in

September last, and this delay naturally puts Dr. Collyer, and others like him who do not belong to India, to a very great expense, and to endless trouble.

If the difficulty of getting rid of the gummy secretions, which must be treated chemically, were satisfactorily got over, we should anticipate a great future for this industry, and Dr. Collyer's machine will certainly be found in the van when this step is gained. Surely this problem is not beyond the skill of our practical chemists, who, we trust, will now more than ever devote their attention to its solution.

The vast improvement that would be effected in the condition of the cultivators of this country by a very slight improvement in the modes of cultivation and the national benefits accruing from such improvement, do not seem to strike our rulers. It is often forgotten that a nation's greatness consists not so much in the wealth and influence of the upper ten of the population, as in the comparative comfort, pecuniary and otherwise, of the great mass of the people, and that when a long series of hard years—the result most probably of imperialistic or autocratic rule—leads at last to a revolution, it is because the masses can endure their position no longer. If our Government wish matters to move smoothly, let them make an effort to improve the condition of the millions of cultivators who form the masses in India. As we have repeatedly stated, startling reforms, even if they are acknowledged improvements, are a mistake; what we want is a very gradual but steady effort towards making two blades of grass grow where only one grew before. Take an illustration of the effect that would follow a very slight increase in production. The present production of wheat alone in India is about 36 million quarters. This is at the rate of 13 bushels per acre, which we take to be about the present average. If this were increased to 14½ bushels, the increase would amount to about one million tons, and the more immediate result to the cultivators would be the receipt by them of about 540 lakhs of rupees per annum for wheat alone, more than they are receiving just now, and who can tell the increase of comfort that would follow to all classes in the country from such an increase in its wealth?

We have received the prospectus of "The Agricultural Institute of Bijnor," an association about to be established by the Rajah of Tajpore, "in the hope of starting earnest and continuous effort for the improvement of agriculture." It is proposed that the institute should, as a commencement, have set before it the following objects: the communication to landlords and cultivators of information about improved agricultural implements or processes; exhibitions; the supply of good seed to cultivators; the improvement of stock, and protection from drought. Mr. Buck, the Director of Agriculture and Commerce in the North-West, has made some useful suggestions for the furtherance of the end the projector has in view, and an inaugural meeting will be held next month. The Rajah has constructed at his own cost a building at Bijnor for the proposed institute, and has arranged to invest Rs. 15,000 in Government securities to cover present expenses.

The report on the Government Experimental Farm at Bangalore for 1878-79 is more than ordinarily interesting, and this is saying a good deal, as Mr. Harman's reports always evince care in their compilation, and give the carefully digested results of intelligent experiments. During the year under review the sickness of Mr. Harman and of his overseer prevented the accomplishment of much that had been arranged for; nevertheless several important results were tabulated. Experiments with the sunflower resulted as usual, nothing decisive having been arrived at. While the plant possesses considerable economic value and grows freely in many localities, the lesson to be drawn from its cultivation here seems to point to our climate being of too forcing a nature. The plant grows with the greatest luxuriance, but the resultant oil is almost always deficient, as compared with the outturn elsewhere. The yield per acre was 450lb. of cleaned seed, which was exceedingly little, and the resultant oil 70lb. or under 16 per cent., while 40 per cent. is not an unusual percentage elsewhere. It would appear that the climatic conditions of India are unsuitable for the proper maturing of the seed, while they force a greater growth of woody fibre than is profitable. An experiment with sugarcane was tried to test the effects of wide planting. The result was satisfactory; the plot, planted 18 inches apart, gave a crop of 75,980lb. per acre, while that put out 36 inches apart gave only 500lb. less. The labour on the latter plot must have been less, and much more room available for hoeing and weeding operations. Another experiment to test the comparative values of different manures was gone into with the following result, in thousands of lb. per acre.

Unmanured	62
27 loads tan-bark	63
77 maunds castor-oil cake	67½
27 loads cattle-box manure	76

All experiments hitherto undertaken intelligently have gone to prove the great value of cattle-box manure. To further test the comparative values of cattle-box manure as compared with manures collected in the ordinary manner by the ryot, a further experiment was tried, which seems to leave no room for doubt as to the value of cattle-box manure:—

	Produce per acre. Maize cobs. lb.	Fodder. lb.
Unmanured plot	3,860	3,680
Ashes of 5½ tons cow-dung	4,620	4,480
5½ tons dry cow-dung	4,480	7,150
5½ tons cattle-box manure	5,870	9,710

Whatever may be the comparative values of a given quantity of cow-dung, and the ashes resulting from the cineration of the same quantity, there can be no doubt as to the great value of cattle-box manure.

Mr. Harman gives some interesting information regarding his recent tour through Mysore, made with a view to inquire into the present condition of agriculture among the villagers, and a comparison of the same with that of former years. He found universal complaints of the destruction of forests which had taken place during the past fifty years. Many of the cultivators told him that in old times they were in the habit of preparing a compost of cow-dung and decayed vegetation of all sorts, an important ingredient in which was dead leaves from forests which have long since ceased to exist; that in those days firewood was available, and that cow-cakes were not so universally used for burning purposes. To use Mr. Harman's own words, "The decrease of forest and jungle causes less fuel to be at hand and forcing the consumption of cattle-dung on the people. The decrease also causes the direct loss in diminished supply of leaves—themselves a valuable manure." This recent dearth in manure has compelled the ryots to substitute low for high class crops. This has materially tended to reduce their profits. Mr. Harman gives an instance of a ryot who had spent some time on a coffee estate, and had seen the benefit of manuring, and who tried bone-dust on his paddy field, by which expenditure he trebled his crop; and he significantly adds, "but even this failed to induce his neighbours to do likewise." Possibly the want of means had something to do with this apparent conservatism. Mr. Harman deplores the disappearance of substantial farmers, and lays it principally to account of the generally more impoverished condition of the cultivation; at the same time he is of opinion that the present system of education—a system which supplies almost everything but agricultural training—is at fault, and we are inclined to agree with him. The ability to use a pen usually leads the student to abjure mechanical work of all kinds as degrading, and it is extremely likely that this has a good deal to do with the decadence which Mr. Harman deplores.

An encouraging feature in connection with native education is the desire now obtaining among a certain class of students to leave the beaten tracks of collegiate training where the only goal is a B.A. degree, and to aim at quite another kind of object. An illustration of the truth of this has been seen in the large numbers who have applied for admission into the Mechanical and Technical School at Seebpore. There is no reason, why that ingenuity so inherent in the Bengalee should not find scope in mechanics much more readily than in preparing

Governmental *nukshas*, or copying out dry official documents. When the Bengalee gives his mind to a profession requiring great mental work, and the exercise of close study and thought, we do not find him wanting, as witness his success in law and medicine, and there is no reason why he should not turn out a creditable engineer. Only to do so, he must not be ashamed to soil his fingers. Our most eminent engineers have all worked hard and served actual apprenticeships to their several professions, and hence in a great measure their proficiency. Although natives make admirable penmen as a rule, we think that putting a pen in a Bengalee's hand is not the best use you can put him to. He pre-eminently among natives seems gifted with a good amount of brain, and in a large number of cases, the opportunity alone is wanting to develop this brain power. The other day two very intelligent youths called on us to obtain information as to the Sydapet Farm, Madras. They expressed themselves as desirous of spending a sufficient time there to enable them to learn improved modes of agriculture; they represented themselves as, and seemed to be, the sons of a petty landholder, and we warmly commended their ambition, which may prove of much more real service to them than all the university honour within their reach.

The *Pioneer* draws attention to a subject we have frequently noticed, *viz.*, the propriety of manufacturing oil in this country, and of retaining the cake for feeding and manuring purposes. There can be no doubt that this is an important question, but we are afraid that nothing will come of it till the cultivators come to understand the value of an improved breed of cattle. A considerable quantity of oil is made in the country already, principally by means of the common revolving mill, but wherever a market can be found, the resultant cake is sold for cash. The oil is made, not with a view to increase exports, but to reduce the cost of the article by manufacturing as near the place of production as possible, and thus saving needless charges in carriage of refuse. The oil is made to supply the local demand, and is largely used for cooking purposes. In many parts of India, notably near the tea and coffee districts, the cake is bought up to be used as manure, and in some places it is used—but to a very limited extent—to feed cattle; yet we find that during the year 1878-79 the following quantities were exported:—

From		Tons.	Value Rs.
Bengal	... ...	9,846	4,64 906
Bombay	... ...	654	37 938
Madras	... ...	5,575	4,82,400
B. Burmah	... ...	195	10,404
		16,270	9,95,648

This cake was valued at Rs. 61 per ton, and this export trade will continue, so long as linseed cake fetches ten guineas per ton at home. However, laying aside the natural supineness of the ryot in this connection, there is another view which may be taken of it, and that is the benefit which the country itself might derive from a more extended oil manufacture. The oil could be extracted more cheaply here, and the carriage on all refuse saved. In the matter of castor-oil, this seems to be the rule followed largely, and it is strange that the same method should not obtain regarding the other seeds.

Dr. Forbes Watson's report on cotton gins, and on the cleaning and quality of Indian cotton recently published, contains much matter interesting to the statesman and the merchant. He divides his subject into three heads—agricultural, mechanical, and commercial. The first embraces the growing of the plant and the means to be adopted for improving the quality of the staple; the second, the means of separating the fibre from the seed so as to injure the former in the least possible degree; and the third, the improvement of the means of communication between the growing and exporting districts, and the prevention of fraud by adulteration. The means of communication can be improved only by the construction of light lines of railway penetrating at different points into the cotton districts, and the improvement of the village roads. As for adulteration we fail to see what the Government has to do with this. The ordinary criminal law of the country, with average intelligence on the part of the exporting merchants, ought to suffice. In jute, for instance, the exporters see every bale packed under the supervision of an agent appointed by themselves, and unless the Bombay cotton merchants adopt a similar system to protect themselves, they need look for little or no help from any amount of specially protective legislation. What is really wanted is improved seed and superior cultivation; this latter including the harvesting of the crop, the quantity of leaf removed from some samples of Indian cotton being as high as 6¾ per cent. That there is room for great improvement in the cultivation no one can doubt. The quality of Indian cotton is vouched for by the price it realises in Liverpool, as compared with the product of other countries. The quantity produced is, beyond question, lower than it ought to be. Dr. Watson calculates the average outturn of clean cotton in India to be 67½lb. per acre, while in America it is 250lb. The proposal as to improvement in seed is a wise one, Dr. Watson deprecating the introduction of exotic varieties. He holds that we have the quality best adapted to our climate, and that we must improve it by a system of pedigree selection. In eight or ten years we should become possessed of a vastly superior article if this plan be followed; although, as we said when speaking of pedigree selection in connection with grains generally, not much can be looked for in the way of improvement, unless the pedigree experiments are conducted under intelligent European agency. Not to appear too sanguine, we do not see why we should not at least produce a fibre equal to a fair American variety, and this without revolutionising our modes of cultivation.

The Persian Company's steam-ship *Henry Bo'kon* left Bushire on the 12th ultimo for Bombay, touching at Galle first, to transfer to the China mail 600 chests of opium, 400 of which have been put on board at Bushire, and 200 await her arrival at Bunder Abass. This consignment forms the remnant of last season's produce. It is estimated that in that season, 7,000 chests of opium have been embarked from the Gulf ports for China and London. The manufacture of this drug in Shiraz, Yezd, and Ispahan has steadily increased year by year, and great care is now being taken to render the quality as pure as possible, so as to preserve the reputation it has recently established in China. It is generally believed that during the next season, *viz.*, from 1st May 1880 to 30th April 1881, no less than 10,000 chests will be forthcoming from the places abovenamed. A wealthy merchant of Bushire has in contemplation a scheme for running steam vessels direct mainly for the purpose of conveying opium.

An Annexation.—The Consul-General of Liberia sends the following:—"By a recent Liberian mail official advices have been received at the Liberian Consulate-General of the annexation by the Republic on the mutual and peaceful terms of that vast and important country adjoining the interior frontier of the Republic, known as the kingdom of Medina. Medina abounds in the richest of African productions; there are thousands upon thousands of acres of gold and iron fields; its forests are teeming with ebony, palm, gum, and rubber trees, while the well-known Liberian coffee tree is found growing spontaneously to the height of 30 and 40 feet in all its native splendour. In this new acquisition Liberia has opened still wider the door into the interior of Central Africa. The Medina Bopora country, with its 700,000 souls, will, with the exception of *the coffee plantations on* the St. Paul's River, form the richest and most populous portion of the Republic. Extraordinary impetus has lately been given to agricultural pursuits in Liberia, owing to the great demand for Liberia coffee seeds and plants in almost every coffee-growing country."

Our Madras neighbours are talking of trying to manufacture paper out of aloe fibre. They possess the aloe in abundance, but they cannot yet make cheap aloe fibre paper. The process was patented in England for the purpose as far back as 1838 by a Mr. Berry. The first cost of the fibre is placed at six annas per viss, by a Madras paper manufacturer, or Rs. 268-12-9 per ton. The local Superintendent of Stationery does not yet consider it advisable to substitute the paper manufactured from the fibre for any paper now in use. He admits that the paper is superior to ordinary country paper, but it is also dearer, and perhaps

above the price which need be paid for paper for the uses to which alone it would be applied. Nor does he think it worth while to make an experiment only to produce paper equal to the sample referred to. A better paper, he thinks, is wanted. And it seems to him that more advantage is likely to be gained by offering a prize for the best paper made from the aloe fibre, with a description of the process and particulars of cost, than by having a quantity of paper produced equal to a standard already attained. But the Board of Revenue do not think that there is any use in going on with experiments unless there is a prospect of paper being produced at a much lower price than that now reported. The Government are of the same opinion.

We have much pleasure in drawing attention to the following experiment as to the value of cattle-box manure. It is taken from the Government *Gazette.* We have always held that manure should be much more carefully stored than is the custom in India, and the esult of this experiment is conclusive on this point.

CATTLE MANURE EXPERIMENT.

The following experiment has been made for the purpose, of bringing forward the difference in value of manure under the system of 'Cattle-box' manufacture adopted on this farm, and of the two common methods of treatment by the ryots in this province.

"The 'Cattle-box' system of housing cattle is briefly as follows:—Over a pit sunk about two-and-half feet in the ground a shed is erected with eves overhanging in such a manner that neither the sun's rays can penetrate (except at an oblique angle in morning and evening) to dry up the manure, nor the rain-fall on or run into the pit, the pit to unduly wet the contents and render it too moist for the cattle to rest on. The cattle are housed in this shed at night, each in a separate compartment, and were supplied, in the case of the present experiment, with grass only. In the morning a little litter, stalks of plants, leaves or unconsumed food is strewn over the box especially where the dung has been dropped, and nothing is removed until the pit is full, when the bulk of the manure is carted away to the field. The top layers not decomposed are replaced in the bottom of the empty pit as litter. In this way twenty loads of manure per annum containing the whole of the dung and urine dropped while the animal is not at work are secured; and bulk is obtained by utilizing any waste substance for litter, thus adding a large amount of organic matter which, placed in the soil, acts as a powerful retainer of moisture.

The cowdung employed in Plot No. 2 was obtained from a grazing ground and placed in a heap for some months until required, the common native method of storing manure not required for fuel. The ashes were the result of burning an equal weight of the same cowdung representing the residuum from the "bratty" or cowdung cake used for fuel throughout India.

The experiment was to test the comparative value of equal weights of each manure. Had the experiment taken the form of using the total amount of manure obtained from a bullock in the same time, the result would have been more striking.

It may be remarked that the dung was from mature cattle fed only on grass, without any gram, oil-cake, or other food, to enrich the manure.

The crop on which the experiment was tried was Queensland maize, grown on a poor light sandy loam. The seed was sown in rows 2 feet apart on the 18th April, and harvested for the sale of the green cobs, 18th of August.

The rainfall during the period of growth was 3·85 inches, but this was supplemented with occasional irrigation from a well as required.

The following are the results per acre:—

No. of Plot.	Manure per Acre.	Green Cobs lb.	Percentage of increase over un-manured plot	Fodder lb.	Percentage of increase over un-manured plot.
Plot No.	I. Cattle-box manure, 5½ tons ...	5,870	+74	9,710	+71
Do.	II. Dry cowdung, 5½ tons	4,480	+33	7,150	+26
Do.	III. Ashes from 5½ tons cowdung ...	4,620	+37	4,480	−20
Do.	IV. Blank	3,360	......	5,650	......

The small quantity of manure employed, the minimum of water used, and the comparatively poor soil to which they were applied, fully account for the light yield, but the comparative result is very clear.

The yield of the cattle-box manure both in cobs and fodder of 74 per cent. and 71 per cent. respectively over the unmanured plot is remarkably high, the manure being well rotted and taken from the lowest part of the pit where it was thoroughly saturated with urine.

The slight increase of 4 per cent. given by the ashes over cattle dung unburned is due to the forcing action of the former; the whole of the constituents being released from the organic combinations, they were held as unassimilable vegetable matter. But as the dung of an animal has been proved by careful experiments in Europe to contain only about one-fourth of the plant food voided in both dung and urine, it is not surprising to find the result of its action far less energetic than when both are combined as in the case of the cattle-box manure. The actual decrease of fodder when ashes were employed is curious. The plants probably suffered under the too stimulating action of ashes from insufficient moisture, though the amount given when aided by the organic matter combined both in the dried cowdung and the cattle-box manure was adequate. The frequent waterings asserted as necessary for maize by native gardeners round Bangalore, are probably largely due to their partiality for ashes as a manure, for on this farm when cattle-box manure is chiefly employed, and where a deeper cultivation is given, crops are raised with a considerably smaller amount.

OFFICIAL PAPER.

ANNUAL REPORT ON THE GOVERNMENT GARDENS AT RANGOON FOR THE YEAR 1879.

BY LIEUTENANT-COLONEL H. P. HAWKES (MADRAS ARMY), HONORARY SUPERINTENDENT.

Dated Rangoon, the 31st December 1879.

HAVING reported in detail on the Government gardens at the end of last year, it will now be necessary to allude only to the more important operations of the year just concluded.

2. One of the old summer-houses, having become unsafe, was removed, and a new one built in a more suitable locality at a cost of Rs. 393-3.

3. The building originally erected for a gardeners'-house having been found to be damp and unhealthy, has been converted into a store-room. In place of this, one of the old tool-houses has been re-roofed, and a second similar building erected: these afford excellent accommodation for the three gardeners on the permanent establishment.

4. The Liberian coffee alluded to in paragraph 27 of last year's report continues to thrive; it is now shewing signs of flowering, and will be in full bloom about the middle of next month. I hope therefore to be able to venture upon some estimate of the probable economic value of this coffee at the close of next year.

5. The mahogany experiment has been an unqualified success. The seeds alluded to in paragraph 29 of my last report were sown on the 7th September 1878. When the plants were exactly a year-old, three of them were measured and found to be 8 feet 3 inches, 7 feet 5 inches, and 6 feet 1 inch in height respectively, with a girth of from 3¼ to 3⅜ inches, a rate of growth which, as far as my experience goes, is altogether unprecedented even in the case of indigenous trees. In addition to this rapid growth, the mahogany tree appears to be very hardy, and promises to bear with impunity the extremes of heat and moisture characteristic of the Burmese climate. Of the last 112 plants raised from seed not one has failed. We have a large number planted out, and they seem to thrive in the poorest soil where it is difficult to keep other plants alive.

6. I believe that this tree has a great future before it. The Forest Department now plant teak almost exclusively, and there is no other tree which can altogether take its place, especially in those situations where structures made of it are liable to the attacks of white ants. But there are many purposes for which a light handsome wood is required; this want would be met by

the mahogany, and there would doubtless be a considerable demand for export.

7. We have also succeeded in introducing a selection of graft mangoes from Calcutta. The first supply of plants, sent down in May 1879, were destroyed by the heavy weather experienced during the voyage, but the next consignment sent in a Wardian case arrived safely, and will be planted out on 1st January 1880.

8. For these mango trees, as well as for a large supply of palms and crotons, the public is indebted to the liberality of Dr. King, Superintendent of the Royal Botanical Gardens at Calcutta.

9. We have had the usual difficulties with gardeners. Of three brought down from Calcutta in May last, two had to be sent back.

10. The heavy rains (11 inches) on the 1st and 2nd November destroyed the early operations in the vegetable garden, and retarded all subsequent planting so much that the outturn of vegetables is likely to be small and the quality inferior. Considering the exceedingly short season during which vegetables can be grown (November to January), and the liability to damage from unusual weather, it becomes a question whether it will be worth while in future years to expend so much labour with the probability of such an inadequate result.

Account current of the Government Gardens, Rangoon, for the year 1879 :—

	Rs.	As.	P.
Cash in hand	873	14	10
Sale of vegetables	134	8	8
" grass and fruit	245	0	0
" toddy	1,410	0	0
By miscellaneous receipts	118	13	5
" local Government	1,000	0	0
" sale of flowers	210	9	6

SELECTIONS.

DR. AITKEN ON FIELD EXPERIMENTS WITH MANURES.

AT the last meeting of the western district of Mid-Lothian Agricultural Association—Sir James Gibson Craig, Bart., presiding—Dr. Aitken, chemist to the Highland and Agricultural Society, delivered an interesting lecture on the agricultural experiments now being carried on by the Society at Pumpherston. Among the large company present was Mr. M'Lagan, M.P.

Dr. Aitken, at the outset, expressed satisfaction at the interest manifested by the association in the progress of the experiments, and it was with much pleasure that he accepted their invitation to explain, somewhat more in detail than was possible at the field demonstration held in September, the results of the recent cropping. He explained that the aim of these experiments was, in the first place, to discover, by practical means, what were the best forms of artificial manures of the various kinds, so as to guide farmers in the selection of what would most economically produce the best crops. The amount of money spent annually in artificial manure was enormous; and it would be admitted by any one that a considerable portion of the sums spent did not yield the returns expected, and that much of the money, though perhaps not thrown away, was comparatively ill applied.

Almost every farmer was experimenting on this subject, and as the result of their investigations, many farmers had arrived at a very shrewd appreciation of the value of the manures they were accustomed to apply; but even the best practical agriculturists were often at a loss, and felt the want of some definite information as to the suitability and productiveness of different manures. The experiments at Pumpherston were an attempt to supply this; and those who visited the station during the last crop must have noticed how very different was the crop-producing power of different manures. The three great classes of manure experimented on were phosphates, potash, and nitrogenous manures. The phosphatic manures were five in number—bone ash, ground coprolites, bone dust, phosphatic guano, and apatite or other mineral phosphate; and they were applied to the soil both in dissolved and in undissolved form. The potash manures were two—muriate and sulphate; and the nitrogenous manures, six—nitrate of soda, sulphate of ammonia, shoddy, dried blood, rape cake, cotton cake; and also various guanos. The great basis of experiment was, that to all the plots on which the manures were being tried, the same amounts of phosphoric acid, potash, and nitrogen were applied; and the only thing in which they differed was the form in which they were applied. If this principle were not kept in view, the results obtained would be misunderstood. The lecturer then explained, by reference to the chart exhibiting the kinds of manures applied to each plant, how the plan was arranged to give precise information as to the efficacy of the various forms of manures, compared with others of a similar class. He then described in detail the result of the experiments with phosphates. The application of undissolved phosphates, except in the case of bones, was very little practised. At the time when mineral phosphates were first regarded as manure, they were dissolved by means of acid; and it has remained the custom ever since to convert mineral phosphate into superphosphate before applying it to the soil. Recently, experiment conducted in Aberdeenshire by Mr. Jamieson showed that the undissolved phosphate, if ground fine enough, was a very good manure, although many had entertained the belief that undissolved phosphates were useless. The experiments at Pumpherston quite corroborated this, as did also the results at Harelaw Experimental Station. This was an interesting fact, and tended to correct a popular error; but the results of the experiments of dissolved *versus* undissolved phosphates had been misunderstood by many. The experiments made in Scotland had not proved that undissolved phosphates were as efficacious as dissolved phosphates, much less that they were better; but they had shown hitherto that they were not so far behind the latter as was usually supposed. Still more at variance with the results of the experiments was the notion that good crops were to be got by the sole application of undissolved phosphates ever so finely ground. The lecturer then showed, by reference to a diagram detailing the result of the experiments at Pumpherston and Harelaw, that undissolved phosphates uniformly produced a smaller crop than the same amount of phosphate dissolved, and that where the phosphate was applied alone the crop was a failure. He also showed how erroneous was the opinion entertained by some who had superficially regarded the experiments, that the fineness of ground phosphates was able to compensate for the want of ammonia or other nitrogenous manure. There was nothing that could make up for the want of nitrogen, and to apply phosphates without nitrogenous manures was a misapplication of money. In the comparative experiments with phosphates, all the plots had received an equal amount of nitrogenous manure, except in the case of two odd plots. The results shewed that phosphates from different sources, when dissolved, gave very similar returns. When undissolved, the slowest acting manure was bones; but that was partly to be accounted for by the less available nitrogenous matter contained in them. There was a strong popular opinion in favour of bones; and though the results of the first two seasons was unfavourable to the application of that form of manure, he believed that future crops would probably show that the popular predilection was not unfounded; and reminded his audience that the results of one or two seasons, and especially of the first two seasons, of experiments, should be accepted with great caution. He then showed that the result of applying dissolved phosphates seemed to be to increase the proportion of water in the crop of turnips, and to a smaller extent in the crop of barley. He also showed that with all forms of manure containing fatty matter, the action was very slow—as, with bones, shoddy, dried blood, and rape and cotton cakes. Speaking of nitrogenous manures, the results obtained showed that nitrate of soda and sulphate of ammonia were about equally effective. The lecturer then proceeded to discuss the merits of the various potassic manures, guano, and superphosphate. He thanked the Association for the interest they were taking in the experiments, and expressed the hope that they would continue to give them their attention, and intimated that he would at all times be glad to hear any suggestions or opinions they had to offer in connection with them, for, while he hoped they had all something to learn from the experiments, he was sure he could not fail to learn much from them if they would give him their co-operation.

At the close of the lecture, a hearty vote of thanks was given to Dr. Aitken for his interesting and instructive lecture.

MANURES.

ANYTHING which, being added to the soil, directly or indirectly promotes the growth of plants, is a manure. Manure directly assists vegetable growth, either by entering into the composition of plants, by absorbing and retaining moisture from the atmosphere, or by absorbing from it nutritive gases. Manure indirectly assists the growth of plants either by destroying vermin or weeds, by decomposing in the soil, by protecting plants from sudden changes of temperature, or by improving the texture of the soil. The manure from cows and all animals that chew the cud, is considered cold and suited to a light soil; that of horses, hogs, and poultry is hot, and best suited to a cold heavy soil. All new and fresh manure engenders heat during fermentation, and has a tendency to lighten the soil, while old, rotten manure is thought to render it more compact and firm. The manure of birds is richer than that of any other animal. Three or four hundred weight of manure of fowls, turkeys, &c., is equal to from fourteen to eighteen loads of animal manure. Guano is manure of this class. It is well to apply about two hundred weight per acre, with one-half the quantity of other manure. Guano should never, in fresh state, come in contact with seeds or roots of plants, as it is sure to destroy its vitality. A thick coat of hog pen or barn yard manure spread on the garden and turned in every spring, will enrich, warm and lighten the ground better than any application of other manures. The principal animal manures are those of the horse, the hog

the cow, and the sheep. Of these, the horse is the most valuable, in its fresh state, but it should be exposed as little as possible, as it beings to heat and lose its nitrogen immediately, as may be perceived by the smell; mix it with other manures, and cover it with absorbents as soon as possible. That of the hog comes next in value, while the cow is at the bottom of the list. The richer the food given to animals the more powerful is the manure. If animal manures are employed in a fresh state, they should be well mixed with the soil and given to coarse feeding crops, such as corn and the garden pea, nearly all plants do better if the manure is composed and fully fermented before use. Bone dust, mixed with ashes or pulverized charcoal, and sown broadcast over the ground at the rate of three bushels per acre, is very beneficial, and the most valuable for, turnips, cabbages, &c., and the quantity needed for an acre is so small, that the expense is less than almost any other application. Common salt at the rate of six bushels per acre, sowed in the spring, on lands distant from the sea shore, not only promotes fertility, but is very useful in destroying worms and slugs Marl, where it can be obtained, may be supplied with advantage, especially to sandy soils. Soot is excellent to drive off insects and vermin. Very little of this can be obtained, but it should be carefully preserved and applied in small quantities to cabbages, turnips, cucumbers, melons, squashes, and all plants infected with insects. Charcoal renders the soil light and friable, and gives it a dark color and additional warmth for early crops. When composted with night soil it becomes *poudrette*, and is second only to guano as a fertilizer. Leaves, straw, and rubbish thrown together, and moistened with a mixture of lime and salt, if kept damp until decomposed, forms the best known manure for trees and shrubs. Swamp muck, mixed with salt, lime, or leached ashes, is of value where it can be obtained, but of still more value is the leaf mold, or black surface soil of the woods. For the vegetable garden, it is best composted with fresh animal manure, but can be applied directly to most plants in the flower garden, many of which will not flourish unless this material is present in the soil. Tanbark, decayed chips, sawdust, and shavings, covered with soil are of great advantage to potatoes. Wood ashes, leached or unleached, may be used with decided benefit as a top dressing to most growing vegetables, especially onions and turnips. Plaster sown upon the growing crop, is good for turnips, cabbages, beans, cucumbers, squashes, melons, and all broad leaved plants. —*D. M. Ferry's Seed Catalogue.*

THE GROWTH OF PLANTS.

THE free evening lecture at the Working Men's College, Great Ormond-street, on February 21st, was given by Mr. Francis Darwin, M.D., a son of the well-known naturalist of that name. Mr. Vernon Lushington, Q.C., took the chair. The growth of a plant, the lecturer said, might be linked to the growth of a snowball set rolling down a snow covered hill side. Both plant and snowball grew in size by the addition of matter; but while, if the bulb of a hyacinth were placed in water and kept in the dark, it would grow in the ordinary sense of the word, in reality the plant would merely have taken stuff out of the bulb and arranged it in a different way, whereas in the growth of an oak tree from an acorn a quantity of new stuff was formed. These instances of growth suggested the questions—first, how a bulb or bean re-arranged its matter in forming a plant, and, secondly, how all the new material was obtained that went to form the tree. He intended on that occasion to speak of only one-half of the question—how the plant in growing arranged its material. First, it was necessary to know what a plant was made of. If 100lb. weight of some growing plant were taken, say turnips, and the water driven off by drying, it would be found that the weight would have decreased by 90lb. and that the solid woody part remaining, about 10lb. in weight would nearly all burn away, leaving but a few ashes. In order to give some idea of the way in which this large quantity of water was held in a plant, Mr. Darwin compared the effect of water on dead matter such as tea leaves or leather with the effect of giving water to a growing plant—the stiff day tea leaves became limp and soft, while the drooping, flaccid stem of a living plant when watered, became stiff and elastic. How could the plant build up a strong, stiff stem with so much of so unstable a material as water, and how did the water become a source of strength to the plant. To understand this they must know how the water was contained in the plant. The solid material was formed into little cavities, and these—an infinite number of little boxes, as it might be—were filled with water. The way in which the water might become a source of strength could be seen by forcing water into a flexible tube or bladder, or by blowing air into an empty glove. The pressure of the water contained within caused the walls of the cells to become stiff. There were other ways, too in which this stiffness was obtained, the water getting into the texture of the woody stuff and stiffening it as water stiffened sailcloth. This state of things existed also in the pith and each cell, being overfilled with water was for ever trying to lengthen itself. Some of the results of these conditions in the plant were then explained by the use of two pieces of spiral spring, and for a more familiar example the audience were referred to the effect of splitting a dandelion stem. Each half curled over outward because the more elastic pith trying to lengthen itself was prevented from expanding on one side by the less elastic bark. With two pieces of spiral spring in a linen tube it was next explained how, when the pressure of water in the cells in the two halves of the pith was not equal, the stem did not grow straight. Not that plants bent accidentally or in a purposeless manner. On the contrary, when the plant bent it was with some distinct and useful object. To the explanation of this point the rest of the lecture was directed. The directions and forms which the root and stem of a young growing plant might take, were happily illustrated with a piece of whitened lead pipe of small bore put through a cork, which did duty for the bean. A great many theories had been offered to account for the fact that the root always tried to grow towards, and the stem away from the centre of the earth. Having related Andrew Knight's ingenious experiment with a revolving wheel, by which, with centrifugal force as a substitute for gravity, the plant was deceived and the direction of growth in seedlings was changed, the lecturer next dealt with the influence of light and damp on the growth of a plant. The stem was invariably shot out or bent aside in order to get at the light and the root, with equal persistency and certainty, was sent to find moisture. It would have been noticed, Mr. Darwin said in conclusion, that he had throughout spoken of plants perceiving the light and knowing where the centre of the earth was, and had used other expressions of a similar kind usually only applied to animals. He had done so with no idea of being paradoxical, but because he thought that by thinking of plants in this way we were more likely to learn what was going on within them. If we would understand the actions of an animal, we must know what was useful or not useful for that life, and it was quite as necessary to consider in the life of a plant of what use its actions were, and in a certain sense why it acted in a particular way.—*Times.*

THE AGRICULTURAL INSTITUTE OF BIJNOR.

PROSPECTUS.

Raises and Gentlemen.

IT has long been my wish to establish an Agricultural Institute or Association, in the hope of starting earnest and continuous effort for the improvement of agriculture. The possibilities in this direction are practically unlimited; but until the large landed proprietors of India resolutely set themselves to the task, no appreciable results are likely to be obtained. It will be creditable to the Bijnor district if it takes the lead in this matter; and you are doubtless aware that the subject is one in which the Government takes the greatest interest, and that any real and practical endeavour to improve the agriculture cannot fail to meet with the sympathy and approval of his Honor the Lieutenant-Governor.

Mr. Buck, the Director of Agriculture and Commerce, has very kindly made some suggestions for the guidance of the proposed Association. In a letter addressed to the Collector of Bijnor, he writes:—

"Para. A. 4.—I suggest that the institution proposed be called the 'Agricultural Institute of Bijnor,' founded by Jaggat Sinha; that it should, as a commencement, have set before it the following objects:—(1) the communication to landlords and cultivators of information about improved agricultural implements or processes: (2) the exhibition of new implements or processes; (3) the supply of good seed to cultivators; (4) the improvement of stock; (5) protection from drought.

"B. 5.—Meetings should be held (not too often, and perhaps once in each half-year would be sufficient). If an organized system be established and carried into effect, some other landlords will see its practical utility and be attracted to join in its operations. At the same time the Institute would be the means of communicating to Government the wants of landlords in connection with cattle-breeding (it may be in the supply of bulls or the grant of a waste tract for grazing or otherwise), without which the endeavours of the landlords might be of much less effect. So also in the supply of good seed which Government has certain facilities for supply.

"C. 6.—A permanent Secretary should be appointed, who would collect from this department, from the Agri-Horticultural Department of Calcutta, and elsewhere, records and papers likely to be of interest.

"D. 7.—Members of the Institute or Association should undertake to give through cultivators on their estates a thorough and careful trial to any new implements or processes submitted to them by the Agricultural Department, and to return a just verdict of their merits or demerits. It will often be as useful to be told that a supposed improvement is useless, and why it is useless, as to be told that it is a success. It is the verdict of cultivators that we require.

"E. 8.—A certain sum should be obtained each year for the purchase of new implements or seeds for trial.

"F. 9.—One annual meeting or exhibition should be held, and prizes given for implements, produce, and stock. I should not advise this being done for another twelve months or so. April is, I think, the best month after the harvest is gathered in.

"G. 10.—The present proposal may be the means of founding an Agricultural Association for the North-Western Provinces. The Talukdars' Association has already taken up a similar proposition for Oudh, and the first meeting is to be held in the first week of next April to discuss future operations."

I have to inform you that I have constructed at my own cost a building at Bijnor for the proposed institute, and have arranged to invest Rs. 15,000 in Government Securities to cover present expenses.

I propose to hold an inaugural meeting next month (due notice of the date will be given). All raises, landed proprietors, and gentlemen, who are willing to join, are requested to send me their names.

BIJNOR:
The [illegible] April 1880.

JAGGAT SINHA,
[illegible]

METEOROLOGY AND AGRICULTURE.

THE study of the general movements of the atmosphere and the investigation of the signs by which atmospheric disturbances herald their approach, and forewarn us, to some extent, of the direction they are likely to follow, are already provided for in France in a special institution richly endowed by the public authorities. But General climatology and the dynamics of the atmosphere, the study of which is intrusted to the Bureau meteorologique in the Rue de Grenelle-Saint-Germain, represent only one side of "the science of weather," the investigation of the *causes* which induce diversities of climates and variations in the appearance of the sky. There is another side which it is equally advantageous to cultivate; the investigation of the effects produced by such diversities and variations on growing crops and on the public health. These two branches of one and the same science are as opposed in the means by which they are pursued as in the object at which they aim.

General climatology requires numerous meteorological stations scattered over the whole surface of the globe. But at each of such stations only elementary barometric and thermometric observations, and notices of rain, winds, and clouds are needed, such as have been collected for the last 200 years. Far different is the case with regard to the study of the effects produced by changes of weather on vegetation or on animal life. Here the number of stations is of far less consequence than the adaptation of the facts observed to their proper object. The field of observation is widened considerably at the same time that it is transformed. In it physiological study and experiment are of considerable importance as a means of learning which of the climatic data are really active, and what are their immediate or remote consequences. None of the meteorological observations made from the point of view of the dynamics of the atmosphere would be of any direct utility with respect to the progress of the crops; they are either too artificial, or too general, or too vague. Hence it is that so little success has attended the efforts hitherto made to found a system of agricultural meteorology.

Theoretical meteorologists put their thermometers in the shade, and do all they can to protect them from external radiation. But our crops do not go on growing under such conditions; on the contrary, they live by radiation from the sky. Solar light, either direct or reflected by the clouds, determine their alimentation. The classification of clouds, the description of their various shapes, are here of no real importance; it is the illumination of plants which it is really essential to recognize and to estimate numerically by appropriate instruments, for this alone is the source of their labour of assimilation. The hygrometric condition of the air acts but very indirectly upon vegetation, plants evaporate very little; they transpire enormously in the daytime by reason of the intensity of the light which impinges on them, and of the water which their roots can imbibe from the soil, and not in consequence of the humidity of the air. Wet seasons are bad years for cereals, not because they are wet but because they are deficient in light.

Heat promotes vegetation and favours the migration which, in wheat for example, conveys from the stalk to the grain the organic elements of which the latter is to be formed; but an intemperate heat may bring about this migration before the elements to be transported are completely elaborated, while a deficiency of heat may unduly prolong the process of vegetation in plants which ought to ripen early.

The influence of certain elements of climate on the success of our harvests, while universally recognized, has often been incorrectly interpreted, or greatly exaggerated. There are other elements, again, the part played by which has been completely overlooked in practice notwithstanding the labours of physiologists, because the means of estimating it have been wanting until quite a recent date. Precisely the same holds good with regard to climatology as applied to hygiene. Consequently it became necessary to institute, in conjunction with the establishment charged with the study of general climatology and the issue of daily weather warnings, another establishment entrusted with the investigation of the intimate connection which exists between changes of weather and the progress of the crops, or the oscillation of the public health. This is the occupation of the Montsouris Observatory, the sole institution of its kind in Europe, where very interesting and valuable work has been done under the directorship of M. Marie Davy. A *résumé* of this labour is drawn up every year in the form of a report. That for 1830 has just been issued, setting forth the results thus far obtained since the commencement of the work, and from this volume the subjoined subject-matter is extracted.

Plants are like cold-blooded animals—their vital activity increases with the temperature. The cultivation of wheat, like that of silkworms, can be perfected in a shorter time, the higher the temperature in which it is conducted. M. Boussingault asserts that wheat, to arrive at maturity, requires a number of days such that the sum of their average temperatures shall form a total of 1,900 to 2,000 deg. This law, which is hardly approached when we use thermometers placed in the shade to indicate the temperature, is verified in the most exact manner, according to M. M. Marie-Davy's experiment, if the thermometer be exposed to the sun instead of in the shade. At the same time it is true only for wheats of the same kind.

We meet with early wheats and late wheats, each variety requiring its own sum-total of average temperature. The soft wheats of Norway, for example, require nearly a third less heat than the hard varieties of Africa. From the state of the temperature in a given place we are thus enabled to predict the dates of flowering and harvest in that locality.

On this point, indeed, agriculturists are rarely at fault. But such is not the case with respect to the quality of the straw and grain. Notwithstanding the prevailing opinion to the contrary, it is not heat but light which operates here. M. Marie-Davy has repaired and brought into constant use the pieces of an instrument once belonging to Dravo which were left behind in the cupboards of the Paris Observatory; this is nothing less than the actinometer with which he measures every hour in the day the sum of the rays falling in the instrument from the sun, the sky, and the clouds, having transformed it into a constant self-registering apparatus. The sum of the materials assimilated by every plant and absorbed into its tissues is in direct proportion to the amount of light it has received. If, at the time the wheat flowers, this amount is a high one, the plant will have amassed abundant materials destined for the formation of the grain; and in spite of any vicissitudes which may occur between the date of flowering and maturity, it may be predicted with almost absolute certainty that the grain will be good and well filled. This relation has already been verified by several years' observations and experiments, and for the last four years it has been practically applied by several of the larger corn dealers of the country in forming their calculations.

In 1875 and 1876 the actinometric degree reported was very high, reaching about 4,600 by the date the wheat flowered. Quantity and quality were very good

In 1877, although the crops looked remarkably well, the sum total of actinometric degrees at flowering time (June 15) was only 4,075 deg. The cereal crops were very middling.

In 1878 appearances were even more favourable, but by June 10, when wheat flowered, the actinometer had registered but 3,660 deg., and a short yield and inferior quality were confidently, and correctly, predicted.

In 1879, on the other hand, the appearance of the crop gave rise to grave anxiety, especially owing to the deficiency of heat; and yet this very deficiency of heat compensated for a deficiency of light. The date of flowering was thereby thrown back to June 21, and thanks to this delay the sum of actinometric degrees had meanwhile accumulated to 4,063; about the amount registered in 1877. Thereupon, M. Marie-Davy was able to announce that the harvest would be far better than had been anticipated in the north of France. In Avignon, the sum of actinometric degrees had risen to 1,80) at flowering date, thus foreshadowing an excellent crop, as it turned out to be later on. On the whole, the wheats of 1879, though far from abundant in quantity, were of fairly good quality.

The influence of the electricity of the atmosphere has not been clearly determined as a part from other factors.

For four years past M. Albert Levy and his assistant M. Allaire have made daily analyses of the air in the park at Montsouris. The object of this investigation is to follow day by day the variations which take place in the accidental elements of air, such as ozone, carbonic acid, ammonia, and nitric acid, so as to estimate the part played by the atmosphere in the nutrition of plants, to determine the influence of such elements on the public health, and to examine whether such variations may not be connected with the mode of circulation of the atmosphere, on which the character of our seasons depend.

This labour was commenced by M. Marie-Davy, and forms the subject of a memoir presented by him to the Institute on January 5 last. At present he deals only with carbonic acid. On this point it appears that, in the midst of incessant changes in the weather, the proportion of carbonic acid contained in the external atmosphere is subject only to oscillations at long intervals in connection with the meteorological character of an entire year. In 1876, a dry light year of good crops, the proportion of carbonic acid was small, about 26 parts by volume in 100,000 parts of air. From 1876 to 1877 the proportion rose a little from 27 to 30; there was increased humidity, a decrease of light, and the crops were less favourable. In 1878, and especially in 1879, the proportion of carbonic acid became large, from 34 to 36 parts in 100,000 of air; these two years were very wet and deficient in light, and on the whole the crops were bad. From October 1879 it began to decline, reaching 25·5 in November, and 24·4 in December. If four years' observations were sufficient in such matters, one might conclude that we are about entering on a cycle of well-lighted years—favourable to crops. Not that the carbonic acid by itself has the least influence on the state of the sky or the transparency of the air. M. Marie-Davy simply sees in this gas an evidence of the general mode of circulation of the atmosphere over the surface of Europe, and an indication of the position and amplitude of the great aërial currents known as the equatorial and the polar currents. The carbonic acid of the air thus becomes one of the most important factors in estimating the general characters of an approaching season, and it will be extremely interesting to see what results will be given by similar examinations of the ozone and ammonia, soon to be undertaken.

One of the questions which has most fully engaged the attention of the Directors of the Montsouris Observatory is that of the part played by water in agriculture. The quantity of water which plants absorb from the soil by their roots and give up to the atmosphere by the transpiration of their leaves under the stimulus of light is very considerable. In an ordinary way, this transpiration is limited by the quantity of water available in the soil; the yield of the crops is limited for the same reason. But it must not be thence concluded that this yield is always

proportionate to the quantity of water given up by the soil to the air through the medium of the plant. Transpiration is but the means to an end, not the end itself. The object is to excite the absorptive action of the roots, and to effect the conveyance to the plant of the materials with which the water in the soil is charged. If the soil be too poor in soluble matters useful to the plant, this latter only exhausts itself by profitless transpiration. If the soil be rich in assimilable products but poor in water, the former are not utilized. To manure land is to leave our work half undone, if we do not at the same time supply the necessary water. In our climate there is no want of water in certain wet years; but if there is a deficiency of light, the plant transpires badly and assimilates little. In hot, dry years water and the materials which it should supply are too often deficient. But where there is abundance of water and of light on a rich soil, heavy crops will be obtained.

Formerly but very moderate crops were exacted from the soil; the land was left to rest for one year in every two or three; marshes and pools of stagnant water were met with everywhere, and the underground sheets of water were consequently fed with a relative abundant supply. At the present time the land is cleaned; standing water is rarely seen; crops are more abundant; and fallowing has been replaced by the cultivation of deep root crops, which absorb the water right down to the subsoil. As a consequence the subterranean waters are less abundantly fed, and the supply from springs has diminished. Constant progress in agriculture is a necessity of the first rank in a country like France, and one of its consequences is to diminish the water-supply, and as agriculture cannot prosper without water it becomes of the first importance to make the best of what there is.

The enormous transpiratory power that irrigation might develop in plants is of peculiar interest for the City of Paris, encumbered with 300,000 cubic metres of sewage water, which she turns daily into the Seine, to the great injury of proprietors down the stream. Several plans have been proposed for purifying this water. Chemical purification, besides presenting practical difficulties, gives very unsatisfactory results, returning to the river the whole bulk of water, with more or less of the microscopic germs and soluble organic matters it contains. Filtration through earth gives much better results. Sewage thus filtered contains but a minimum of its organic soluble matter; but its volume is only very inconsiderably reduced, while all the manure in it is lost though recoverable in the filtered liquid in the form of nitric acid or ammonia. In these respects the cultivation of plants on the filtering surface represents a distinct progress. Experiments made by M. Marie-Davy on the 800 superficial metres of growing vegetation placed at his disposal by the Municipality of Paris, in the gardens at Gennevilliers, showed that very little of the water employed in their irrigation ran off by the drains and was lost, nearly all of it being given up to the atmosphere by evaporation and transpiration from the plants grown on them; only one-tenth of the water used escaped their action. Similar results were observed in a course of four months' weekly irrigation experiments carried out at Montsouris. While profiting by the sewage water and the manure contained in it, vegetation has therefore the effect of accelerating the evacuation of the water given to the soil, of promoting the aëration of the latter, and consequently of hastening the nitrification of the organic refuse thrown upon its surface.

The microscopic germs which abound in sewage water further contribute largely to this result. In fact, on submitting to comparative analysis the water that had drained off from plants irrigated two or three times a week with sewage, and that from plants similarly treated with rain or Seine water only, it was found that the former is quite as poor in organic nitrogenous matter as the latter, only containing a larger proportion of nitrates and mineral salts. The whole of the manure is nitrified in both cases; but, in consequence of the large doses of sewage employed in the former, the vegetation was unable to utilize all that it contained.

Analysis of the air circulating over the surface of the irrigation fields at Gennevilliers showed, among other results, that though this air contained more organic matter than that in the Montsouris park, the excess is due to the far greater number of cryptogamic spores which are present in soils that are frequently irrigated. These have no baneful influence whatever on the public health; while the germs of bacteria, several kinds of which are dangerous from this point of view, are actually less numerous than in the air of Montsouris. There should therefore be no hesitation as to the possibility of purifying the sewage of Paris by the soil, especially if we consider how enormously its purifying action is enhanced by cultivation, and how it in turn is enriched by the manure it abstracts from the sewage. No kind of danger to man or to the health of stock fed on sewage-grown crops can possibly arise if the operations of irrigation be properly conducted. —*L'Echo Agricole.*

MANURE EXPERIMENTS UNDER GLASS.

IT may be accepted as a hopeful sign of the times that, notwithstanding the great difficulties in the way of farmers in their individual capacity successfully conducting scientific experiments, several of them have applied themselves to the work of testing in a scientific manner, the comparative utility of different forms of manures. Prominent among the Scotch farmers who have engaged in this kind of inquiry is the name of Mr. Scott Dudgeon, Longnewton, St. Boswells, who has followed up his experiments with oats under glass, conducted in 1878, by another set of experiments carried on last year with phosphatic manures in the growth of barley in pots under glass. The results are set forth in the report to hand of the proceedings of the Chemical Agricultural Association of Scotland. The leading inference drawn from the oats experiments was 'that the proportion of phosphorus present in a manure it matters little whether in its natural state or acted on by acid (that is dissolved or undissolved from coprolite or from bone), exercises a material influence on the yield especially of grain. The subsequent experiments have been solely devoted to the further elucidation of this inquiry. Mr Dudgeon has, like many of his co-experimenters, occasion to regret that the results are disappointing, having regard to discrepancies between individual pots of the same group where uniformity was expected. Investigations of this nature will not, however, have been in vain, even if they do no more than establish the necessity of procuring as many duplicates as possible in experimenting, before accepting as facts of national and general application what may have reference only to local and particular circumstances.

The experiments with barley have been conducted in the same pots and within the same erection as were used for the oats series —under a glass roof with the sides open and protected by three-quarter-inch wire netting. The pots, 88 in number were ranged in the centre of the structure. Each pot was made as far as possible the exact counterpart of every other, and the conditions as to soil drainage, seeding watering, thinning out, &c., were assimilated. The seed, chevalier barley was sown on the 29th April, when the dressings of manure were applied; and on the 21st of May the plants were thinned to the number of ten to each pot. In July the ear appeared, and in October 21 all were ripe enough for cutting. Three manures were used in the experiments, viz., bones, bone ash, and coprolites, these being used in their natural state, ground or crushed, and again in their dissolved state after being acted on by acid. The amounts applied were regulated according to the proportion of phosphorus in the different substances, as analyzed by Mr. Falconer King. Five pots received phosphate of lime in the form of bone meal, five in the form of bone ash, five in the form of coprolite, five in the form of dissolved bones, five in the form of bone ash superphosphate, and five in the form of coprolite superphosphate. In addition to these there were four pots which received an application of half the phosphate in the form of coprolite, and the other half as coprolite superphosphate, and the remaining four pots received no phosphate of lime. In order that all might be placed in similar conditions regarding nitrogen, each pot (with the exception of the two which got no phosphatic dressing) received an application of nitrate of soda, in the proportion of about a cwt per acre.

The results, as shown by the subjoined table, differ somewhat materially from those recorded in the case of oats. The great advantage in produce as shown by the average of the reliable pots, would in this instance appear to lie with the application of bone ash superphosphate at a cost of 38s. per acre, whereas in the case of oats a loss was recorded from the use of this form of manure. Next in order of increase come dissolved bones, which in the former set of experiments resulted in a considerable deficit. Mineral superphosphate ranks third, as compared with a former failure. Fourth in point of yield we have coprolites finely ground. In 1878 also they were found to be a profitable application.

Among the more notable features of these experiments is the failure of the bone meal application, and the favourable position assigned to the application of manures in the dissolved form. The previous experiments conducted by Mr. Scott Dudgeon pointed in the same direction, the produce of dissolved bones with Peruvian guano and muriate of potash standing then highest on the list as regards profit, with one exception, *viz.*, well-rotted farmyard dung. These manures were used in the first instance to test the source of nitrogen, and on this occasion are dispensed with.

Regarding the conclusiveness of these experiments, there may, and doubtless will be, diverse opinions. The objection will be urged that, having been conducted under glass they are not likely to afford a reliable guide as regards the unsheltered products of the open field. But the advantages of such a mode of experimenting should not be altogether overlooked—*viz.*, uniformity and regularity of the soil, the easier allotment of manure, greater facilities for observation and thinning, regulation of moisture and protection from the ravages of beast or tempest. Mr. Dudgeon will no doubt be the first to admit that it is difficult to lay down a hard and fast rule amid so many varying circumstances of soil and climate. In closing his interesting report he says:—'I forbear making any remarks or drawing any inferences from the results. They speak for themselves, and it must be confessed are disappointing, because they exhibit great discrepancy between individual pots of the same group (even after every allowance is made for diseased heads &c.) where uniformity was to be expected. One thing they teach, the great necessity there is for many duplicates in experimenting, and how careful we should be in not hastily drawing conclusions from single or isolated instances. It must only be by repetition and re-repetition that the truth can be discovered. Let us not then be discouraged, but still persevere.'

The thanks of the agricultural community are due to Mr. Scott Dudgeon, and men like him, who encounter the giant difficulties connected with work of this kind. Whether these agree or disagree with other experiments, it is well to have as many carefully conducted tests possible, in as many different localities as possible. It is indeed a question which might well engage the attention of our national agricultural societies—Whether individual farmers ought not to receive pecuniary assistance and encouragement in carrying out labours of this kind for the general good? In this way the character and requirements of so many

different soils and climates might be accurately ascertained. To show that there is considerable room for action and reform in regard to this vitally important matter, it may be mentioned that a tenant farmer experimenter not long ago expended £80 on analyses of soils, manures, &c., in connection with experiments whose results he embodied in a report, for which the Highland and Agricultural Society paid him the handsome sum of five sovereigns!

The following is the table of results referred to in the foregoing remarks:—

No.	Manures.	Quantity, Cwts per Acre.	Cost per Acre.	Produce, being average of all Reliable Pots in each Series. Equal to per Acre— Bushels of barley.	Cwts of Straw.	Increase over Nothing in Grain.
1	Bone ash, finely ground ... and nitrate of soda ...	2·35 1·08	39s. 6d.	31·1	23·9	5·7 bush.
2	Bone ash superphosphate ... and nitrate of soda ...	4·01 1·08	38 0	48·1	35·0	19·7 ,,
3	Coprolites, finely ground... and nitrate of soda ...	2·82 1·08	2[illegible] 6	34·7	23·2	6·3 ,,
4	Mineral superphosphate ... and nitrate of soda ...	4·85 1·08	34 10	36·6	24·8	9·2 ,,
5	Bone meal ... and nitrate of soda ...	2·91 ·383	27 8	25·6	19·3	(Decrease 2·8 bush.
6	Dissolved bones ... and nitrate of soda ...	3·91 ·571	35 10	33·0	25·0	9·6 ,,
7	Coprolites finely ground ... Mineral superphosphate ... and nitrate of soda ...	1·41 2·42 1·08	39 8	33·7	22·8	5·5 ,,
8a	Nitrate of soda ...	1·08	14 0	33·4	22·2	4·9 ,,
8b	Nothing ...	—	—	22·4	21·5	

In the above it will be seen that the quantities of manure applied to each pot have been calculated so as to give the cwts per acre. Then follows the cost of the different applications per acre, these having being valued by the usual standard per unit of ingredients, according to analyses. The produce of grain and straw is next given, the bushel being computed to weigh 56lb. In striking the average some pots had to be omitted owing to diseased heads.—*North British Agriculturist.*

REPORT ON THE BOTANICAL AND AGRICULTURAL GARDENS OF JAVA.

WE have received a copy of this Report (published early) and we proceed to notice and translate such portions as are of most interest to Ceylon readers:—

THE AGRICULTURAL GARDEN.

After reporting various changes and improvements in the establishment, and giving a list of persons and gardens which have sent contributions, Mr. Scheffer,* the Director, states that the agricultural garden is progressing. A note informs us that this garden, in extent about 70 hectares, (*i.e.*, about 173 acres), was founded in 1876 as a branch of the botanic garden, and that in the same year there were planted in it besides the different varieties of coffee mentioned further on ½ a bouw (about 7 acres) each of *sûriyan* trees, balm of Peru, *kapok* (*Eriodendrum anfractuosum*) vanilla, legumes, *widjen* (sesamum), jute, &c. In 1877 they were planted, besides the ordinary plantation of rice, ½ bouws of *Coffee Polyspermum C. Preanger, kosambi, Calliandra spec.*, Cochin China cinnamon, nutmegs, cacao, oil, palms, *ramih*, and grasses, so that at present the fixed plantation extends to more than 15 bouws (210 acres), without reckoning the ground occupied by annuals. The report then goes on to give details of the experiment made with different plants at Tjikeumeuh, Tjibodas, and Tjisaroewa.

THE BOTANIC GARDEN.

The botanic garden establishment is composed of the following separate gardens:—The botanic garden proper at Buitenzorg, 800 feet above the sea; the agricultural gardens at Tjikeumeuh, near Buitenzorg, 800 feet; Tjisaroewa, 3,500 feet; Tjibodas, 4,500; Tjibeureum, 5,500. The last three are situated in the Preanger residency, on the side of the Gedeh mountain. After descriptions of the ploughs used, statistics of the school of agriculture, and an account of the trial of bees, the director proceeds to give the results which have attended the planting of *Eucalyptus globulus*, which is being used by the Government for the reforesting of the mountains in Java. In spite of white-ants, caterpillars, and the burning of the forest by the natives, the trees are growing well and successfully. The trial of the *Eucalyptus alba* in the low-country was a failure, the plants not coming up owing to want of proper supervision. *Eucalyptus piluluris* suffered much from cockchafers and was slow in growth; other species of *Eucalyptus* were tried with various success. Of the *juar* (*Cassia florida* VAHL.) Mr. Scheffer speaks very hopefully especially for reforesting under 1,000 feet. It has been recommended as a shade for coffee, but was thought to be injurious. The *suriyan* (*Cedrela febrifuga* BL.) was planted alternately with cinchonas and eucalypti, and proved very successful: the wood is said to be good for tea-boxes.

ALBIZZIA MOLUCCANA.

The demand for seed of *Albizzia moluccana* was very great. Of this tree Mr. Scheffer says:—"The culture of *Albizzia moluccana* is very easy. It is sown in hothouses or nurseries. The seeds are soaked in water before sowing. It is well-known that most of the coffee planters in Java employ fullgrown forest trees as shade for coffee. In some situation, this proceeding appears to me unnecessary, in others it is destructive, but the plantations are situated in circumstances so varied as regards climate and distribution of rain in the different months that it would be very imprudent to lay down a general rule. For shade the dadap (*Erythrina spec*div.) is generally employed. Although this tree is preferable to those which are used in Ceylon (where, *e.g.*, the *Artocarpus integrifolia* is much employed) it has many drawbacks. In the first place the dadap, which is always propagated by cuttings, soon rots at the lower extremity of the trunk; then it suffers much from the larvæ of a *cerambyx*, which eat the pith and cause the death of the tree; besides, the leaves are largish and end in elongated points which form as it were watercourses, by which the rain always falls in the same spot on the coffee trees; finally, the dadap has too bushy a foliage and does not attain to any considerable height. The *Albizzia* on the other hand grows more quickly; it gives a shade which is placed at a considerable height above the coffee trees, which allows a free current of air; its foliage is not too thick and the leaves are divided into numerous folioles of small dimension. Further, the folioles, as is always the case with mimosas, are pendant and turned downwards during the night, so that the dew and the moon's rays can penetrate to the plantation. For reforesting, if only an amelioration of climate is in view, or firewood is required, I know of no tree better than the *Albizzia*. Mr. Dennison planted it in order to obtain firewood for his limekilns, and he writes to me that he has no culture more profitable. Trees of three years old were large enough to furnish planks of sufficient dimensions for a box containing 70 kilos of tea." The Director received very varying reports as to the benefit of this tree, some saying that it gave very little humus and no shade, while others report the exact opposite. There is no question, however, that the tree is very fragile, but Mr. Scheffer states that this fault may be remedied by thoroughly pruning the tree when young. A Mr. Winsser reports that the plant is slender that the shade is too dense, that the branches are too horizontal and too low, and that consequently the tree hinders evaporation, and thus gives rise to many evils in the coffee. Mr. Scheffer answers these complaints by saying that if the plant is slender, the other statements can be true, and if the latter statements are true, the complainant has not followed the directions given as to pruning. A Mr. de Haan cut down some trees for firewood, and he obtained excellent charcoal for his tea-house.

VARIETIES OF COFFEE.

Reports on trials of camphor, guttapercha, cassia, nutmegs, cacao, and oil-palms (*Elæis guinensis*) follow, and then comes this statement with regard to coffee:—

"The plantation of different varieties of coffee, opened at Tjikeumeuh, and mentioned in my last report, is in good condition.* Besides the 13 varieties named in the reports, a half bouw of polyspermous coffee and Preanger coffee was planted; so that there are in all 7½ bouws planted with coffee. From Mauritius two further varieties were received, of which one, called Leroy, is found to be the same as that which here is known under the name of Laurina. The other, called Victoria, is as yet unknown. We hope soon to be able to multiply this variety. During the extreme and unusual drought, many of the coffee trees appeared to be in a very bad state. Many trees lost their leaves, which the drought had yellowed. As soon as the rain commenced, however, these trees recovered in a surprising manner, and very few plants died. In the month of November the soil round the plants was dug up with the

* We regret to have to notice that Dr. Scheffer has died since this article was received.—ED., *I. A.*

* This plantation has an extent of 6½ bouws [A bouw is 14 acres.—ED., *C. O.*], of which half a bouw is occupied by each of the following species:—large moka, small moka, laurina, angustifolia, Aden, Woengoe-Kadoe, Mauritiana, Menado coffee, with monospermous fruit, Padang coffee, and Liberian coffee. Besides there has been planted the *jambos* coffee, a very reliable kind, found in the old coffee gardens near Sookaboemi, and which seems more productive than the other kinds. Finally, half a bouw was planted with plants produced from very large seed gathered at Tjikeumeuh. Of this last species again the largest seeds will be gathered, and by repeating this process several times it is hoped that a large-beaned variety will be got. All the seeds were sown in March 1876. The plants were put out in December 1876 and January 1877.

pick, and each plant received about 5 kilos of good cowdung. In beginning of July the following varieties began to flower;—the large beaned coffee from Tjikeumeuh, the Padang, the monospermous species from Menado, the Mauritiana, the large moka and the small moka. The prevention of the blossoming was tried, by removing the buds and flowers, but this operation had to be given up: 1st, because for about 3,000 plants, this labour took too long; second, because, as soon as the first flowers were removed, other opened. Only half of the trees of each species were pruned. Half of the pruned plants were put under shade, the other half were exposed to the sun. The influence of shade has given no conclusive result this year. The pruning was begun by nipping off some of the lower primaries, but the drought arrested the growth and gave no satisfactory result. In December the same process was repeated, and the result was different in the different species. On the Mauritiana the nipping had no effect, and no secondary growth developed. On the Woengoe* variety only some rare secondary branches appeared, and we may say that the nipping gave no result. On the other sorts (Tjikeumeuh, Padang, Menado, monospermous, and large moka) many secondary growths developed, but the same result was experienced on the unpruned trees, and especially on those with primaries, which had suffered from the black blight, of which I shall speak later on. The Aden coffee gave many secondary shoots after the nipping. The trees which had not been pruned gave less, but still a pretty large quantity, many secondary shoots on the plants which had been nipped had to be cut off. On the small moka the same thing took place. This operation was not performed on the Laurina, as this species always gives too many secondaries. The effect of this experience is therefore mostly negative. The results may be thus summed up:—some species gave no secondary shoots, even after the nipping; some others produced shoots, but quite as many without the nipping. There are other species which without nipping produced a good number, and there is even a sort which without nipping produced too many secondary shoots. As soon as the wood of the primaries is ripe, we shall try by pruning them, to force the trees to produce secondary shoots, if they do not produce sufficient by themselves. The same experiments were tried on some Padang coffee trees, which happened to be outside the regular plantation. We had received these plants in March 1876. In the case of some only the development of the second shoots was regulated, in the case of others the branches were cut pretty short. We cannot judge of the result of this operation until the crop time, which should take place at the beginning of 1880. In the places where the first shoots had been cut the secondary branches developed regularly. These were again nipped and gave consequently abundance of fruit. With the exception of the Liberian, the coffee trees at Tjibodas have grown well, but they have not yet blossomed. The plantation of *Maritiana* coffee of Mr. Blokhus (see preceding report), containing 884 plants, has prospered exceedingly well, notwithstanding the want of rain. In 1877 the plants were 3½ feet high. The crop obtained by Mr. van der Meer at Ternate was pretty satisfactory, and he got 58 to 60 cents. per ½ kilo in Europe. The bean was small, but much sought after in German commerce. As to the Laurina coffee, the reports which have reached me are those of the residents of Madioen, Solo, Samarang, the Preanger Regencies; from the Assistant Resident of Painan; and from Messrs. Blommenstein, Boers (Repacking, Bojolali), Blokhuis, Hudig (Remves, Kendal, J. F. van Leeuwen (Semo, Bojolali), Pietermaat (Madjalegka), and de Sturler (Tjomas, Buitenzorg). The opinion of different planters regarding this species does not agree. The opinion of Mr. de Sturler, who possess a 2,000 plants at an elevation of 1,800 to 2,000 feet is not favourable. "The tree, according to him, is small, the branches are too close, the berries are small, and the crop is very poor. Its taste, it is true, is very bitter. At Wonogiri (Solo) the plantation of this kind has been considered a bad speculation, and it is said that the crop is less than that given by ordinary coffee. The planters kept it for their own use on account of its superior aroma. On the other hand, the plants in the private garden of the *controleur* of Bandoeng, although the situation of the garden is unfavourable, produce quite as much as the ordinary Java coffee. It is said that this kind of coffee fetches a higher price in the markets. I have not been able to test this fact, but its aroma is generally praised, and the market will not be slow to appreciate it at its true value According to certain reports this species of coffee is a native of Sierra Leone, and was planted largely in Mauritius, where it is known under the name of Leroy coffee. I hear from there that it is better suited to elevated regions, and this opinion appears to be confirmed by the plants at Tjibodas, which grow more vigorously and are less compact.

Liberian Coffee†.

The progress of our plants of Liberian coffee* leaves nothing to be desired. As was said in the previous report all the trees had to be transplanted on in the beginning of 1877, having been too closely planted at first. Not a single plant perished through this operation, and in spite of the extraordinary drought which immediately followed.

Our plants correspond very closely with the description of Mr. Hiern (On the African Species of Coffee, in Trans. Linn. Soc., 2nd ser., Bot 1., p. 171), but the beans received in 1874 were much larger than those figured by Mr. Hiern, and also than those received from England followed only a few plants appeared to suffer for a time; since then they have been perfectly healthy. My opinion, that the absence of primary bud, on the lower part of the stem was to be attributed to the fact of our plant having been kept too long in the pots, proved to be correct the young plants, afterwards transplanted, produced from cuttings of the original plants, do not exhibit the same defect. The blossoms which opened at the beginning of 1877 set well and gave some fruit at the beginning of 1878. The first important and general blossom took place in July 1877, and the fruit, which appeared in large quantity, was gathered in 1878. In each axil he cherries are found in such large number that in my opinion it is impossible that they will have good large beans. The fear, therefore, that each axil would produce but few berries has proved groundless. The still green berries are 15 to 27 millimetres long by 12 to 21 broad. The same trees on which are these berries had another large blossom in Feb. 1878, on the branches produced in 1877. At the elevation of Buitenzorg, therefore, Liberian coffee appears to blossom twice a year, in February and July. As has been mentioned above, between the blossoming and the maturing, there is a lapse of twelve months. This leads me to believe that this coffee will succeed better at a lower elevation than Buitenzorg. The multiplication of this species of coffee by cuttings, tried at first with good results, proved afterwards to be very difficult. A number of cuttings were put in nurseries, both under glass and uncovered, and in beds both warmed and cold, but in the course of the year scarcely one struck root. However, few died and all the remainder formed callosity. The rainy season brought a better state of things, and we were able to remove from the nurseries many cuttings having roots. The very young cuttings, with still green wood and short joints always succeeded best. We possess about two thousand cuttings without roots. Besides the 115 cuttings, with roots, which existed at the beginning of 1877, 27 were fit to be planted out, so that actually the whole of our plantation is composed of 332 plants in the open, 25 cuttings with roots, and 2,000 cuttings more or less without roots. The 25 cuttings, which have taken root, will be transplanted, with 13 others as soon as they have got stronger, so that our plantation will consist of 360 plants, which, planted 10X10 feet, should cover the

---

* A variety produced in Java. It is distinguished by dark-red leaves.

† As the Liberian coffee is of recent introduction, and as it promises to gain the preponderance over ordinary coffee, I believe I shall be doing well in giving here the history of its introduction into Java, drawn from my reports for the years 1873 to 1876. In 1873 I proposed to the Government to get from Liberia seed of the species of coffee indigenous in that country, and the quality of which was highly praised. Through the help of our Consul at Greenville (Mr. N. J. A. Maarschalk) we received in 1875 four small boxes filled with seed. At the same time, Mr. Maarschalk informed us that the large-beaned trees were very rare and that for this reason he sent me only a small quantity of seed. On measuring them, I found them (they were still enveloped in the parchment) 22 millimetres long and 12 mm. wide. The other boxes contained beans of smaller size. Unfortunately in spite of the greatest care, not one of the seeds germinated. In 1874 some Liberian coffee trees were successfully introduced into Ceylon, and Mr Thwaites, with his usual kindness, offered me several plants. But as the coffee leaf disease had manifested itself in Ceylon, and as the plants introduced from Liberia were all infected with it, I dared not accept the offer. I therefore proposed to Government to make a fresh attempt and to ask Mr. Maarschalk to sow the ripe beans in wardian cases and transport them in this manner. This advice was followed, and the result was that in October 1875, we received a sufficient quantity of healthy plants. All the seeds had germinated during the voyage, and not one of the plants was dead Shortly afterwards I received another case of young plants from Dr. Hooker of Kew. Unfortunately, the young seedlings were not yet fit for transplanting. We proposed to plant them in the new agricultural garden at Tjikeumeuh, which would shortly be at our service. For this reason they were kept in pots for a longer time than was desirable. They leaves of the young plants were 30 centimetres in length by 12½ in breadth, and their base was more uniform than that of ordinary coffee. In the same year we received a quantity of seed from Liberia, of which none germinated. In 1876 the garden of Tjikeumeuh was granted, and in February I transplanted 118 plants, after having first had holes dug, which were afterwards filled with earth of good quality. Not one was lost, and at the end of 1876, they had already attained a height of the 4 to 5 feet. At the beginning of 1877 the first blossoms appeared, and as at first only one flower was found in each axil, whereas in ordinary coffee a number are found, it was feared the produce of the Liberian coffee would be very small. However the succeeding blossoms appeared in great number in each axil, and the carpels were well fertilised. Nevertheless our plants had one defect. In the ordinary varieties (except the small moka) the lower primaries usually very prolific spring from the stem at a little distance from the soil. In our Liberian coffee plants the lower primaries were 2 or 3 feet distant from the soil. I believed this fact to be owing to the planting in pots in which we were obliged to keep them too long, and which hindered the natural growth. The base of the stem produces many adventitious buds, and I attempted to employ them for multiplication by sowing them as in Europe the buds of some trees are sown. These trails met with no success. However a portion of these buds were allowed to grow, and the young sprouts were used for cuttings. This preceeding was more successful, and at the end of 1876 we were able to transplant 20 plants produced from cuttings, whilst we had in the nurseries 115 slips with roots and 200 without. The spacing of trees is 10X10 feet. Several plants were transported to Tjisaroewa, and Tjibodas, in order to test the influence of a colder climate. This influence was fatal, and nearly all the plants died; a result which accords very well with the information received from Liberia.

surface of half a bouw. This plantation once made, the remaining cuttings can be sold, as soon as they have taken root. We have noticed no influence caused by the shade on the coffee trees. The blossoms of this species of coffee differ exceedingly among themselves, in the length, breadth, and number of petals. However, these different forms are usually found on the same tree, and have no connexion with the form of the fruit which on each plant is always the same. According to the fruit, we may divide our plants into four principal forms, distinguished from each other by the demension and the form of the base of the style, which, after the fructification and the falling off of the corolla, remains attached to the carpel. In the first form the base of the style is long and almost conical; its lower part is as large as the circumference of the calyx. In the second, the base of the style is of the same length, but it has a cylindrical form, and it is not so wide as the calyx. In the third form this base is almost as broad, and it is also of cylindrical form, but at its lower part it is suddenly contracted, so that there it is much narrower than at its upper part. Lastly, in the fourth form it is small and narrow. Two varieties of each of the first, second, and third form may be counted: one with nearly round fruit, and the other with the fruit oblong. Of the third form we possess only the oblong variety, which is very remarkable for its dimensions and which seems to produce the largest fruit. In each variety the fruits of elliptical form are always larger than those of nearly spherical form. It is usual to speak, as of two different species, of Liberian coffee and Cape Coast coffee, without however being able to indicate the characteristics which distinguish them. We have received from Kew plants of the two species, and an analysis has shown me that if the names are partiarcul there is no difference between the plants. It is true that all the plants of Liberian coffee, produced in Kew, bear fruit of the fourth form, but this form is found in the Cape Coast coffee plants. The other Cape Coast plants have the second form of fruit. Rather that assert that plants with an erroneous name have been sent as Cape Coast coffee, I would believe that there is no difference between these two species, the rather that the Liberian also has several varieties. The plants which we received direct from Liberia through the medium of our consul display all the form of fruit mentioned. Nevertheless, these plants as a rule give a larger fruit than those which we received from Kew and London, and as British India and Ceylon have been furnished exclusively* by Kew and London, I venture to think that we possess better varieties of Liberian coffee than those of other tropical countries: the more that all the plants of the best variety (the third form of fruit) have reached us direct from Liberia. In multiplying the mother plants by cuttings and seedlings, we shall in future note the variety to which they belong, and so we shall be able to see if the form of the fruit is hereditary. As a good number of varieties have been derived from the ordinary Java coffee (*e. g.*, the red coffee), so it may happen that the Liberian will also produce new varities in our island† It would be very useful to profit by this disposition to try to improve the species. In accordance with the preceding facts, during 1877, we were not able to distribute a single plant, whether to Government or to private individuals, except in cases where a very advantageous occasion presented itself of exchange for other plants or seeds. In the course of 1878 we shall probably be able to dispose of a large number of cuttings and a quantity of seeds, a portion of which might be reserved for private cultivators. However, the demands of the latter are so numerous, that it will be difficult to find a fair method of allotment, and I think the best way will be to divide this quantity into a number of little portions, which will be sold by public auction, for the profit of the agricultural garden. Another portion of these seeds and plants may be used by Government for an experiment on a larger scale. It will be better to make large experiments in one or two localities, and to place in charge a special employé, who will be certain of not being replaced during the earlier years, than to send a small number of plants or seeds to several localities and different employés, who are continually changing their stations, and who consequently cannot take upon themselves the responsibility of the plantation. Experiments should be made in Java, where the seasons are more pronounced, and also in Sumatra and Borneo, where the rains are more regularly distributed during the year. The two coffee trees, which survived out of those planted at Tjibodas (at 4,500 feet elevation) are not flourishing: they are rather retrograding; however, Mr. de Sturler of Tjomas, informs me that a tree planted by him at 2,000 feet, is growing very well and bearing fruit abundantly. On the part of private persons there have been many attempts to introduce the Liberian coffee. Messrs. Muller & Sons of Rotterdam, who also helped in the transport of our plants, sent to Messrs. J. F. van Leeuwen & Co., in Batavia, considerable quantity of seed, which, being sold by public auction, obtained unheard of prices. I had not much confidence in this importation, having myself several times received seed from Liberia, of which not one germinated. Therefore only a small quantity was bought by the Director of the Department of the Interior, who sent me the seeds, asking me to germinate them and then divide the plants between several employés. But of all these seeds nothing came up, and I learn that none of the other purchasers was more fortunate. At last, to ascertain positively if it would really be impossible to succeed in importing seed in good condition, I asked Mr. Bull of London to send me some seeds by way of experiment. I had learnt that seed sent by him to Brisbane had germinated. However, this correspondent informed me that he was not importing any more seed, but only plants; that he had formerly sent to Liberia a person of trust to gather and pack the seed with all possible care, but that none had grown. In Ceylon also several attempts were made for this purpose, but with the same negative results. However, the importation of plants always succeeds. Many private agriculturists have received plants from Mr. W. Bull. A planter at Solo formed a project of sending a person to Liberia to procure plants. Messrs. Moormann & Co., of Batavia, before knowing that the disease called 'coffee leaf disease,' attacked the Liberian coffee trees as well, had ordered from Ceylon a number of plants, which were imported at Batavia in October. Immediately I advised these gentlemen to burn all the plants, seeing that no inspection or analysis could determine whether these plants did not carry with them the spores of the disease. My counsel was immediately followed. Government indemnified those gentlemen, and the introduction of coffee plants from Ceylon was prohibited. Mr. W Bull also wrote me that a Ceylon planter, who had gone in person to Liberia, had told him that the Liberian coffee tree produces ten times as much as the ordinary Ceylon coffee. He asserted that the Liberian coffee obtains in commercial markets on account of its superior aroma, double the price of ordinary coffee: that at the first picking the Liberian tree gives only a small quantity of fruit: but that afterwards 20 to 24 lb. a tree are obtained. Mr. Dennison of Koeripan, also gave me information received by him from Ceylon. The only plantation where the Liberian coffee is being grown, is situated at about 1,400 feet elevation above the level of the sea. A crop of 2 to 3 tons per acre (48 to 72 pikuls per bouw) is talked of, but a year elapses between the blossoming and the maturity of the fruit, which is attributed to the low temperature of the climate; a plantation in the low-country has been tried, with good results at the beginning. Mr. Sonderegger, of the firm of Moormann & Co., Batavia, himself visited Ceylon, and informs me that on an estate at Kandy, they had already had a crop of about a ton an acre (400 trees, so 4 katis per tree, 20 pikuls per bouw), but that afterwards there was still so much on the trees that he reckoned that at the end of crop, double this figure would have been obtained.

(*To be continued.*)

* The vast bulk of the plants now in Ceylon are from seed received direct from Liberia.—Ed., *C. O.*

† And in Ceylon.—Ed., *C. O.*

AGRICULTURE IN MADRAS.

THE quinquennial statements of Agricultural Statistics for Madras for the five years ending 1876-77 have recently been laid before the Secretary of State. The returns are said to be not more unsatisfactory than was to be anticipated from the occurrence of the famine during the latter part of the year under review. Notwithstanding, however, the fact that in several districts people were compelled to resign a large quantity of land in consequence of the famine, there was a net increase on the whole in the occupied area of 271,000 acres, or about 1·4 per cent., part of which increase appears to have been due to more accurate measurements and part to the cultivation of land hitherto unoccupied. There is still a wild field for the extension of cultivation, as it appears that nearly ten millions acres of assessed waste, or about half as much land as has yet been brought under cultivation, is still available to meet the wants of a growing population. Assessments increased, partly from revision of settlements, partly from extension of the area in occupation, by over eight lakhs during the quinquennial period. Considerably over twenty lakhs appear to have been expended during the period comprised in the statements by Government and by private persons on new works of irrigation, the new wells alone constructed by private enterprise exceeding 80,000 in number. On the other hand, there was a serious decrease, caused by famine, in agricultural stock, while the statistics of occupancy appear to indicate that the sub-division of landed property is making rapid progress.

AGRI-HORTICULTURAL SOCIETY OF INDIA.

THE usual Monthly General Meeting was held on Thursday, the 25th March 1880.

W. H. Cogswell, Esq., V. P., in the Chair.

THE proceedings of the last Meeting were read and confirmed.

The following gentlemen were elected Members:—

His Highness the Maharajah of Burdwan, Dr. R. F. Swaine, Messrs. H. Pratt, L. G. Middleton, James Hutchinson, Edwin Kock, and Harry Morison.

The names of the following gentlemen were submitted for Membership:—

Major J. Liston, Depy. Commissioner, Lalitpore,—proposed by Mr. J. W. Quinton, seconded by the Secretary.

Lieut. A. Connell, Asst. Engineer, Fyzabad, Oude,—proposed by the Secretary, seconded by Mr. W. H. Cogswell.

T. J. Cumming, Esq., Merchant, Kurrachee,—proposed by the Secretary, seconded by Mr. G. L. Kemp.

Philips White, Esq., Depy. Commissioner, Jaloun,—proposed by Mr. J. W. Quinton, seconded by the Secretary.

W. A. Court Beadon, Esq., Supdt. of the Central Jail, Midnapore,—proposed by Mr. W. Cornell, seconded by Mr. F. Wilcox.

Andrew Ker, Esq., (Messrs. King, Hamilton & Co.) Calcutta,—proposed by Mr. G. L. Kemp, seconded by the Secretary.

Manager of the Rampore Tea Garden, Cachar,—proposed by Mr. H. F. Brown, seconded by Baboo P. C. Mittra.

Contributions.

A small collection of grass seeds. From the Director, Royal Botanic Garden, South Adelaide. Plants and seeds from the Nicobars. From E. H. Man, Esq.

Seed of Alphstonia excelsa and Stenocarpus Cunninghami. From L. A. Bernays, Esq., V.P., Queensland Acclimatisation Society. Mr. Bernays writes that the former is a good bitter bark, and the latter a very beautiful tree with crimson flowers.

Seed of Eucalyptus globulous and Grevillea annulifera. From Baron F. Von Mueller. The following is extract of a letter forwarding the above seeds:—

"It affords me much pleasure to send you some Euc. glob. seeds at least sufficient for tests in various places. I have no means of collecting these kinds of seeds on an extensive scale; indeed all kinds of Eucalyptus seeds 'en gros' are now articles of trade by seed merchants. The seed of E. globulus has risen in price as gradually, the native trees in the forests become extensively felled; it used to be 15 shillings per pound, but cannot now be got for less than 18. But one pound contains seeds enough for a multitude of thousands of plants. If therefore any Member of your Society wants to rear on *an extensive scale* it could be easily calculated at what price the seeds might be got in the Melbourne market, where I will be happy to procure them and see that they are fresh and correct to name."

A collection of Cucurbitaceous Maize and other seeds. From Captain J. F. Pogson. These seeds are available to Members. (Full particulars regarding them will be found in the body of the proceedings.)

Garden.

The Head Gardener's Report was read as follows :—

"The weather has been seasonable, though the rough south-west winds have caused rapid evaporation, thus requiring extra labour in watering the plants which we are obliged to keep in pots to be ready at a moment's notice for any orders that may come in. We have re-established the water communication with the west tank so as to free as many hands as possible for potting off young stock, and arranging the same; also to bring all the fruit trees into one section of the garden, such as Mangoes, Lichees, Peaches, Limes, "forbidden fruit," Anona, Loqout, &c., of all of which we have a very fair stock. Members' orders to the number of 63 besides many supplemental ones have been executed since the opening of the year 1880, exclusive of sales to non-members. Of Palms we have a large stock, especially Caryota of kinds, which when planted out in a garden, are extremely useful, as they grow fast and their foliage is elegant when compared with surrounding shrubs. Of Araucaria Cunninghami, we have about 20 fine plants averaging 6 feet in height. During the cold season many Palms and Araucarias, &c., were successfully moved to new sites as they were becoming crowded. One corner of the garden which was originally covered with jungle has been planted out with Agaves, Fourcroyas, Euphorbias, Cacti, &c. The large Plant House near the dwelling has been repaired and enlarged, the size now being 110 feet in length by 38 feet in breadth. I however propose that we might have separate houses for Orchids, Ferns, Dracænas, Crotons and miscellaneous plants, so that members and others would be saved from loss of time in making their selections. Of new Marantas and Crotons we have a fair stock in hand, also a large stock of Alamanda of kinds, extremely showy plants for lawns as they stand the sun well. Six Plantains presented by C. Ady, Esq., of Moulmein have been planted out on the north side of the Kitchen Garden. This plot of land, I think, might be utilized for the trial of vegetables, but must in the first instance be heavily manured as the soil is very poor. We have many Janipha Manihot plants in hand. The west tank near the principal entrance should be excavated early this year as soon as the water gets below zero. Of Liberian Coffee we have 140 plants available; the seed sent on the 6th of January 1880, from Munzeerabad (Madras Presidency) has not yet germinated fully. Of Mahogany plants we have only 28 left of those sent by W. H. Cogswell, Esq., and 170 of our own sowing. We have only 34 Avocado Pears left. The flower bed should next year be distributed more equally around the Garden grounds where space permits, instead of in one special place near the west gate, which though introductory is certainly unsuitable on the north side of the entrance tank, the flower beds having been arranged under the Mangoe trees some years ago. New Rose beds will be formed around the central lawn and other positions as opportunities offer. Caladiums are being started, preparatory to potting off, they are therefore available for a short time. *Contributions.*—A large quantity of house-rubbish has been placed at our disposal from the Collectorate compound, Alipore, being closely adjacent to the Garden, and will prove extremely useful for repairs of walks. Manure of good quality is being steadily and gradually carted from the Stud Depôt, Garden Reach, through the kindness of Major Roberts. Anæctochilus sp. (gold veined leaf), presented by O. Weynton, Esq., in company with orchids and other plants, the first named is doing very well, the remainder fairly good. The Anæctochilus having been kept in a cool place without any glass protection whatever and being liberally supplied with water, have succeeded very well in the sand and moss into which they have been transferred. We really require a large supply of moss for numerous purposes. Members who are placed in situations suitable for the collection of moss might respond to this request.

Mr. Gleeson also sends lists of Rose plants recently received from the Allahabad and Agra Gardens, which have reached in good order. Those from the Lahore Garden have been but partially successful; while those from Mr. Bull of London have unfortunately proved a failure. A list of 20 rare plants transferred to the Royal Botanic Garden, Howrah, is also appended. These consist principally of Anthuriums also Marantas, Cumerias, Alocasias and Aralias.

The Gardener likewise forwarded a box of cut flowers of Petunias, Phlox, and Verbena raised from seed contributed by Messrs. Sutton & Sons, and sown on 3rd December last. These were all much admired.

The Secretary also placed on the table some plots of Phloxes and Asters of superior kinds. Flowers of the latter measured nearly three inches in diameter.

New Plough.

A preliminary Report was read from a Sub-Committee of the Council on a new plough manufactured by Mr. W. Martin of Etawah. The Committee state that this plough made by a common native mistry, costing four rupees, and weighing about 12 seers, was tried at the Society's Garden with an ordinary native plough costing two rupees. "The trial lasted about half-an-hour. The bullocks and men employed for the first 15 minutes on Mr. Martin's plough were transferred to the native plough and *vice versa*; but the cattle and men, in both instances, appeared to work with greater ease with the native than with Martin's plough. The trial was only so far determinable, as the man and cattle who worked on the new plough were evidently quite unaccustomed to the extra weight thrown on them by the mould board in the act of inverting the sod. Another great drawback was the dry and hard condition of the land. For this and other reasons, it was agreed to have another trial under fairer auspices on as early a date as possible. It was, however, evident to those present that the plough had considerable merit and did its work well, breaking the soil fairly up with one ploughing. Your Committee are not prepared to add more to this report, the trial being a partial one, and merely preliminary."

Resolved.—That another trial, with such other new ploughs as may be offered, be undertaken at commencement of rainy season.

Experiment with Cattle Manure.

Submitted a Resolution of the Government of Bengal on the subject of trials with cattle manure in reference to recent experiments at the Farm at Bangalore, and suggesting that probably trials of a similar nature might be undertaken at certain localities in Bengal; whereupon it was resolved that a Sub-Committee, consisting of Drs. Barry and Lynch, Messrs. Cogswell and Stalkartt, be appointed for the purpose of suggesting the best means of furnishing the Government with information on the subject of manures.

Kotegurh and its Agricultural Products.

The Secretary next submitted the following interesting paper from Captain Pogson, in reference to the various kinds of seeds alluded to under the head of contributions :—

The value of Kotegurh over Simla as a sanatarium is simply incalculable, and when it is borne in mind that the water running from hundreds of springs is as pure as can be, whilst the air is absolutely untainted, cold and dry, conditions due to its perpetual descent from the snow-clad Himalayas, the apparent neglect with which these priceless gifts of nature are treated by the public in general, and the sick in particular, is very remarkable.

Kotegurh Church has an elevation of 6,400 feet above the level of the sea, and the river Sutledge, visible from its door, is 3 200 feet above that level, whilst Mount Huttoo, on one of whose stupendous spurs Upper and Lower Kotegurh is built, has an elevation of 10,400 feet, and as all the North-Western spurs slope towards the Sutledge, the scientific and practical Horticulturist and Agriculturist has it in his power, by a judicious selection of sites and altitude, to grow all kinds of tropical fruits and crops on the banks of the Sutledge, and European fruits, flowers and vegetables at various altitudes; for every 530 feet of ascent gives a change of soil and climate, and accounts for rice, cotton, mangoes and plantains growing at Kapoh, and superb English apples, and other European fruits at Buraree, (Upper Kotegurh), whilst all kinds of American maize and pumpkins, choice English flowers and vegetables, as well as the Jooar of the plains, and the Imphee or sugar-cane of China, thrive in my newly made garden a hundred feet or so below St. Mary's Church.

The pleasing task of improving the indigenous agriculture of the locality rendered it necessary that I should seek and secure the aid of the authorities, and through them of zemindars, whilst in the Rev. Mr. Rebsch, of the Kotegurh Mission, and Rev. Mr. Carleton of the American Mission at Arnee, I had most valuable supporters and fellow-labourers. I am greatly indebted to Baboo Goodroo Mull, who, in addition to being a zemindar, in possession of large ancestral holdings, is the Tehsildar, of the important iron-producing district of Kot Khai, as well as of Kotegurh.

The New Orleans and Sea Island Cotton seed obtained by me from the Agri-Horticultural Society, were made over to Baboo Goodroo Mull, who caused them to be sown on land owned by him at Kapoo on the right or Kotegurh bank of the Sutledge.

[Mr. W. H. Cogswell, a member of the Cotton Committee, has kindly favored the Society with the following report on the samples sent by Capt. Pogson :—

Sea Island unginned, good color but a little stained, good and regular in length, silky but of weak and brittle staple, probably occasioned by being grown at such a high elevation.

New Orleans, ungiened, excellent color, staple fair and of good length, but wanting in strength. The same remarks apply to this as regards elevation in the cultivation].

In the samples submitted herewith, we have part of the first crop of these cottons ever grown within the Himalayas. The Paharees are greatly pleased with both kinds of cotton, and *now* I shall have no trouble in getting them to grow these, in place of the indigenous kind, therefore in due course pray send me all the cotton seed you can share for distribution to applicants. I may mention that weavers of cotton and wool are by no means scarce in these hills, hence the production of superior cotton wool will have a most beneficial result.

The varieties of Maize alluded to were—*1st*, 'General Grant's Corn;' *2nd*, 'Golden Sweet Corn;' *3rd*, 'Stowell's Evergreen Corn;' *4th*,

'Moore's Concord Sweet Corn;' *5th*, 'Mexican Sweet Corn,' and *6th*, Early Canada Field Corn.' These seeds were given me by the Rev. Mr. Carleton.

Mr. Duthie, Superintendent, Government Botanical Gardens, Shaharunpore, in answer to my application, sent me as follows :—1st, 'Yellow Canada Corn;' 2nd; 'Red Cuzco Maize;' 3rd, 'Striped Cuzco Maize,' 4th, 'Yellow Cuzco Maize;' 5th, 'White Cuzco Maize;' 6th, 'Mammoth Sugar Corn;' 7th, 'Gourd Seed Corn,' and 8th, 'Red Indian Corn,' and as all the above came to maturity, whilst the seeds were largely preserved for this year's sowings, I have every reason to hope that from Kotegurh as a centre these superior kinds of maize will gradually find their way into the hands of zemindars, and be cultivated far and wide in place of the very inferior indigenous maize of these hills.

In making my division of these seeds, I gave Rev. Mr. Rebsch a supply and kept a portion for myself, and our joint crops have been most successful, the smallest number of cobs on my plants (manured with bone-ash, and limestone in powder) being three, and the largest six, and in many cases so heavy were the cobs, that the growing plants broke down under their weight. As I was much pressed for room several kinds of maize had to be sown in one plot of land, and the result has been most curious, for the 'Red Indian Corn' and the 'Red Cuzco Maize,' have, in numerous instances, hybridized the other kinds: thus I have cobs of yellow Cuzco Maize, with numerous single seeds, and groups of seeds of a deep dull purple colour: white maize with pale pink and striped seed; the stripes in some cases being pink, in others red or reddish. I have some cobs in which there are white and yellow grains, more or less striped red, and a few seeds of deep purple amongst them: thus showing treble impregnation, and indicating of possible means of improving the ordinary maize of the plains by crossing it with the red and striped Cuzco Maize, both kinds ripening seed early, and bearing cobs, thickly and perfectly supplied with fully developed seed. I find I have forgotten to mention the 'Golden-dust Corn,' which you sent me with three other kinds, the former bore abundantly and a good supply of seed has been preserved, and the latter were sent to Kombarsun to the Rana's *mallee*, whose report has not yet been received. The Jooar (*Sorghum vulgare*) of the plains, it was stated, would not grow up here, and being of a contrary opinion, I obtained some seeds, which were sown, the plants grew well, and the crop of ripe seed harvested has dispelled the popular fallacy connected with the subject. In like manner, it was affirmed that gram (*Cicer artinum*) would not grow here, and this fiction was similarly disposed of. The price of gram is never less than two annas a seer, and six seers of it per rupee is the price during the season when travellers have been fleeced by the bunniahs, who being directly interested in the matter, do not at all approve of my small gram field, or that of the zemindar who is growing it at my suggestion, with seed supplied by me, the price demanded being beyond his means.

I now come to my pumpkins, of which I have three superior kinds, the flesh of all being of a deep golden color, crisp and firm, the smell and taste exactly resembling that of good cucumber, and as all have been so eaten, uncooked, the value of the fruit is apparent. All are very good to eat cooked in various ways, and all make very nice preserve. No. 1 produces round fruit, the skin being milk-white. No. 2 is called the Turban Squash, and has kept perfectly since last October, and No. 3 is the Giant Pumpkin of Chili.

Rev. Mr. Carleton sent me four seeds of it, all of which germinated and flowered profusely; the constant rain interfered considerably with the impregnation of the fruit flowers, and a good deal of perfectly formed fruit was in October destroyed by frost, and during the rains by some insect. Five pumpkins of various weights, ranging from five to thirty pounds, were cut and eaten, one large pumpkin of over forty pounds was stolen by a Paharree, and I had five matured pumpkins when the frost set in. These were cut and weighed as follows :—No. 1, 131lb. 10½oz; No. 2, 120lb. 5oz.; No. 3, 95lb. 4oz.; No. 4, 75lb. 3oz.; No. 5, 52lb. 7oz. Total weight 474lb. 13½oz.

I have the pleasure to present the Society with three hundred seeds of this monster pumpkin known at Kotegurh as the *Maha Kuddoo*, and I also present seeds of the two other kinds and, in addition, a packet of *Chirata seed*, for experimental culture in England, where it should answer.

I have forwarded in the parcel two cobs of Maize: the dark red striped cob shows how well this variety grows up here, and the yellow as a good specimen of crossing.

I trust some Members of the Society will try the experiment of improving the common maize of the country by hybridizing with the red striped kind and report the result, and I will do the same, and if by our joint exertions the numbers of cobs per plant as well as the grain is increased, a positive boon will have been conferred on the people.

Letters were read—

From Mr. T. B. Fernandez, Superintendent of the Revenue Survey, Bhernagore, reporting the result of his sowings of the Bamia Cotton from seed received from the Society, and sending a small specimen thereof.

From Mr. W. Foley, submitting specimens of tobacco raised in Sylhet from seed received from the Society, and of a fibre and cloth made therefrom from the "Kaddeema" tree (*Villebrunea appendiculata !*)

Baboo Pertab Chunder Ghose reports favorably of the tobacco. The fibre possesses great strength.

Further particulars regarding the latter to be supplied by Mr. Foley.

INDIAN TEA.

AMONG the various articles of export from this country tea takes a place in the front rank, and although the imports into the United Kingdom (the chief market, at present, for Indian tea) have increased from 17,278,000lb. in 1874, to 38,488,700lb. (or 122 per cent.) in 1879, and the amount consumed per head of the population (allowing for increase of population), from ·55lb., per head in 1874, to 1·037lb. per head in 1879, or an increase of 84 per cent., still from various causes, some of which, together with their remedies, we will try to enumerate, Indian tea of the present time does not stand well in the English market and its outlook is anything but rosy. In regarding the price at which an article must be sold in the retail market, we must take two standpoints, the producer's and the consumer's, and endeavour to find the price from them. In looking at the matter from the tea planter's standpoint, we will presume that he can produce tea, and sell it with a fair margin of profit at the plantation for a certain price per lb., say *a*. On his selling the tea it passes through various hands, each expecting a commission on it, and its value is further increased by the various charges of duty, freight, insurance, loss in weight, &c., until it reaches the hands of the retail dealer, who finds that he cannot sell it *to the consumer* with a profit to himself, under a price per lb., which we will call *b*. Bearing these facts in mind we will now look at the matter from the consumer's point of view.

The average consumer says :—"I am willing to pay a certain price per lb. for my tea," which we will call *x*, this being so, if the price of tea rises above *x*, the demand from consumers *decreases*, and, as a consequence, stocks *increase*, and the price of tea falls to somewhere about its normal level. It becomes necessary then for us to work backwards from the price *x* the consumer will buy at, and endeavour to find out from this, at what price the planter must sell at to ensure the public demand, and so his own profits, being kept up; we will suppose that deducting the cost of freight, insurance, duties, commissions, profits of middlemen, &c., from *x* the price the consumer will give, he must sell his tea at a price per lb. we will call *y*; in short that the difference between *x* and *y* represents the profits of the men through whose hand the tea passes until it reaches the consumer, plus the charges, such as duty, freight, insurance, &c., if he would sell his tea at all, and it behoves him therefore, to use every possible form of economy. The charges which we have enumerated as being imposed on the tea after leaving the planter's hands are not capable of much reduction, as many of them are not profits on the tea but items such as freight, duty, commission, and insurance which *must* be paid before the tea reaches the consumer.

Remembering that *a* and *b* are the prices the planter and retailer can respectively sell at profitably; when the price *b* is arrived at from *a* as basis of calculation; and by an inverse process of reasoning that *y* is the *price* at which the planter must put on the market if the public are only prepared to give *x*; we arrive at the following facts:—

First, if such a happy state of things exist that the prices *a* and *y* are one and the same, the planter and all others concerned make their profits, and the consumer is satisfied.

Secondly, if *a* be less than *y*, increased profits accrue to all concerned; but as *b* is less than *x* the retailer, however shortsightedly, probably raises *b* to *x*, after which in time the increased profit is spread through the different hands the tea has passed through, the shares of profit however going in a decreasing ratio from the retail dealer towards the planter; for it nearly always happens that the producer is the slowest to feel the advantage of a rise, and the quickest to feel a fall in the value of the manufactured article, of any of the hands through which it passes.

Thirdly, supposing *a* to be greater than *y*, or in other words that the *cost of production of the tea*, is too high, what must the planter do? He must either sell at a loss or reduce the cost of production.

Now we greatly fear that what the Indian tea trade is now suffering from is this, that cost of production is too great. The only thing the planter can do to try and make a profit is to use the strictest economy, to exercise the most careful supervision, and to sell *every scrap* of tea to the best possible advantage. Here comes in the question of markets. The English market will only take the best stamps of tea and as it will not pay a high enough price for the planter to make a real profit, on this his best tea, if his lowest classes remain a drug on the market, he must try and find a profitable market for his commoner qualities at present unsaleable on our English market. By doing this he relieves stocks and will command a better price for his good teas in consequence of the general character of Indian tea on the English market being improved by the withdrawal of the lower types. The question that now comes before us admitting that a market is wanted for these low teas, is: "Where is this market to be found?" We answer with confidence, in Australia.

There, people have not reached such a degree of fastidiousness as they have in the old country, and the lower classes of Indian teas are in good demand. What is wanted for them is a better circulation, more "pushing" to use a term often found in advertisements for commercial travellers. Indian tea only wants to be thoroughly known in our colonies to be thoroughly appreciated; and the advantage to the planters by a ready sale for the lower classes of teas would be enormous. It would in the course of a few months clear off those stocks of tea in the United Kingdom which are daily growing larger, and which as Indian tea, owing to the rapid drying practised now-a-days, (which compares with the slower method formerly in vogue very much as Indian tanning does with English), deteriorates very greatly and very rapidly by keeping, are anything but profitable to their holders; it would by this clearance obtain a better demand, and therefore a better price for the finer tea which would alone represent India in the English market.

Another thing for planters to remark is, that ever since the present "pungent rasping flavour" insisted on by the brokers, and given by rapid drying, was imparted to the tea, stocks have steadily increased, so that it is reasonable to suppose that, great as the advance of Indian tea in public

flavour has been, it would have been still greater had the old flavour been adhered to. In addition, too, we must remember that the process by which the pungent flavour is imparted to the tea is probably the cause of the Indian tea of the present day deteriorating so much in quality by keeping. This argument that the increase of stocks is due to the pungent flavour being introduced is justified by the fact that, while the tea had the old flavour, the public taste increased as the imports, and therefore, stocks remained stationary; but as soon as this flavour called very aptly "rasping' was introduced, immediately stocks rapidly increased from 1874 to 1878, this increase of stock being 24½ per cent., while the demand of 1879 was 5 per cent. below that of 1878; the reverse being the case for China teas. Undoubtedly one of the evils which numbers of tea planters have to contend with is this: they are not able to sell in the best market; they are not able "to hold." "How does this arise?" our non-business readers will ask. The answer is simple enough. So many men on entering a business with a fixed sum of money at their disposal, representing all their available cash, are far too prone to invest too large a proportion of this sum of money in the machinery, or the land, or the mines, or the goods, as their trade may be; in other words *start on too large a scale.* Take for instance a man who buys a new empty mill. Say he has capital sufficient to fill two-thirds of it with the best cotton machinery and leave him a handsome balance for working expenses. Now numbers of men instead of doing this, and filling up the mill as their business increased, would fill the whole of the mill with machinery at once and, if sufficient funds were not left to carry on the business, they would obtain an over draft from the bank, or an advance in the shape of a mortgage on the property. This overdraft or this mortgage too often forms an incubus that can never be shaken off. The advance from the bank (readily enough given in most cases), is probably negotiated when trade is slack and money cheap, and the borrower thinks that trading with money borrowed at, say, 3 per cent. is a good business (we are here speaking of English mills which we have taken as an example of our meaning of "over buying"), but when trade revives and money becomes dear, the unfortunate borrower finds his debt to his banker (which cannot be wiped off all of a sudden, however great a rise may occur in prices) bearing interest at, say, 6½ or 7 per cent. or even more, and cutting a large hole into those increased profits he was building his hopes on. In the same way a tea planter, too, often "over buys" or "over grows" the amount of land he should purchase or the number of acres he should put under cultivation, with his capital. Consequently, as the time approaches for the tea to be gathered and dried, he finds the cash in hand or at his bankers running short, when in comes the curse of the trade, the insidious "middleman," who offers either an advance on the crop at an exorbitant rate of interest, or, if the planter be poor enough and weak enough, he buys the crop in advance from him; of course to considerable profit to himself. Now the curse of these middlemen is that they bolster up the weak men of the trade (we are now looking at the subject from a planter's view), and having bought at a low price from the impecunious producer can afford to sell under the market rates and so lower them. A trader is always entitled to a fair profit on the money he has invested, and he would always obtain it, were his fellow tradesmen all men of sufficient *available capital* to be able to afford to hold their goods until they could dispose of them at remunerative prices, but as there are in all trades, men whose business are too large for them (and therefore who are weak men) the buyer can always obtain the goods he wants from one of these men who cannot afford to keep a heavy stock. They must have their money turning over and over to keep going. Now if these weak men had only been content to start on a smaller scale, they would have been among those who could afford to wait for remunerative prices, without altering the amount of their capital; if they had bought less land and had less under cultivation their expenses would have been smaller and their available cash balance greater.

To those then starting a tea plantation we would say:—"Start in a small way and keep a good balance at your bank for working expenses, avoid all commission agents, middlemen, and loan givers as you would the father of evil; use the strictest economy compatible with *thorough* efficiency; sell your very commonest tea or any rubbish you may have with as much care as your very finest; do not be in a hurry to plant new ground and extend your business until thoroughly satisfied that it is worth it, and you are able to afford it." To those in the hands of middlemen of any sort, to the little men with the big business we would say: "Throw off the man you are in debt to, at all costs, if possible, even by selling, if you can, part of your estate; once out of the hands of moneylenders, keep out."

To prosperous men who owe no man anything and who know not what it is to feel short of capital, we would offer no advice beyond this, which we offer to all tea planters.

Combine, if necessary, and rid the trade of those useless agents, &c., who stand between you the producer, and the public the consumers, of your produce. You cannot get rid of them all; you can get rid of some; when your tea passes through so many hands you do not know what may or may not happen to it, and the fewer hands your tea passes through the better for it, the better for you and the better for the public, who would probably get a better article, at a less price, and yielding better profit to its producers than at the present day, if some of these go-betweens could be done away with and the producer and consumer brought nearer to one another.—*C. & M. Gazette.*

MINERALOGY.

IT is surprising that the mineral wealth of India should have been so systematically neglected for a long series of years past. The reader of Indian history does not need to be told of the importance of gold and silver mining in ancient times, and in fact the remains of old workings testify yet to the energy displayed in those days in the prosecution of this industry. India was known as a land of gold and silver; now it has become a land of poverty; where, too, are the famous diamonds for which this country had such a name, and where the justification for the now almost obsolete phrase "the wealth of India?" We are now on the eve of another effort to recover our lost ground in this respect, and we hope that the mania which has taken possession of us for gold-*mining* will not entirely blind us to the more valuable coal workings all over the country. It cannot be doubted that the East Indian Railway Company is largely indebted to its cheap and plentiful coal supply for its profitable working. Doubtless geographical position and careful management in its several departments have something to do with this success, but that a large percentage is due to cheap coals cannot be denied. From a recent return we find the average cost of coal per ton to be as follows:—

	£.	s.	d.
East Indian Railway	0	5	5
Bombay Lines	1	10	0
Madras Lines	1	15	7
Oudh and Rohilkhund	1	9	11
Sind, Punjab, and Delhi	2	2	8
Average of Guaranteed Lines	1	7	7
" State Railways	1	11	7
General average of all	1	9	7

A glance at this table will show in a large measure why the East Indian Railway working expenses are 34·91 per cent. of gross earnings, while the average of all the guaranteed lines is 52·73, and of some of them as much as 76·05 per cent. We may be told that the coal which India yields is not good, and is usually in out-of-the-way regions. The quality is certainly not nearly so good as that of English coal, but it is sufficiently good to be perfectly practicable where space is not a material object. It does not last so long as English coal, and much larger quantities have to be carried. This is not so great an objection on railways where short journeys can easily be arranged; but it is objectionable for steamers, especially when long voyages are the rule. Nevertheless many steamers use it mixed with equal portions of English coal. In some parts of India we have a coal repeatedly said to be in all respects equal to English. This remark refers particularly to the rich veins known to exist in the Khassiah and Jynteah Hills of Assam; the only objection to the working of this coal hitherto having been its distance from the places of consumption. This difficulty is, however, in course of removal. The extension of the Northern Bengal State line towards Dhoobree has reduced the difficulty materially and the ultimate extension of this line eastwards towards the Upper Assam district will further reduce it, while the opening of the proposed extension of the Eastern Bengal line to Mymensingh, and ultimately to Cachar, will entirely remove it. Besides, if it be considered unprofitable to bring that fine coal to Calcutta, there can be no doubt that a large quantity will find a market on these two lines, as well as on the steamer lines on the Assam and Cachar rivers. Nor must we forget to notice the discovery that two districts in Madras have been found to abound in copper ore, which on analysis yields an abnormally high percentage of pure copper, the actual figures being 42½, as compared with 5 per cent. obtained from Cornish ore, and 20 to 30 from Cape copper.

ENCOURAGED by the success of the pioneer company, another has been brought out, called the Indian Glenrock Gold Mining Company, with a capital of £100,000, to acquire and work 3,000 acres containing reefs of auriferous quartz, which adjoin the property of the South Indian Company; and, in order to give the project every chance of success, the two companies are to be united under one management, saving both expense and loss of time. Writing on the 27th ultimo the London correspondent of the *Bombay Gazette* says: Although the prospectus of the Glenrock Company was only issued a day or two ago, I believe its shares are already virtually subscribed, and they will assuredly go *pari passu* to the same premium as the South Indian Company's. The Bombay people must know pretty well what these properties are worth, and I do not pretend to be able to tell them anything new on the subject. All I can do is to report what is passing here, and therefore I point out that,

assuming Mr. Brough Smyth's opinions as an engineer to be sound and to bear the test of actual mining, there is some chance of furor for Indian gold mining shares here during the next month or two. Of course spurious schemes may be started to profit by the popularity of the sound ones, but so far as the South Indian and the Glenrock Companies are concerned their success is assured, and they have every prospect of a brilliant future.

As an instance of the way in which recent discoveries have affected the value of land in South-East Wynaad, the Ooty correspondent of a Mofussil paper states that he knows of an instance in which one landed proprietor made a small fortune in a very short time. "He sold a coffee estate for Rs. 50,000, where perhaps he would not have realized a fifth of this sum but for the land being rich in quartz. This same gentleman very recently bought one piece of land for Rs. 500, and in less than half-a-dozen months sold this identical land for Rs. 18,000! There are now in Wynaad to my knowledge two or three planters, who, as soon as this gold mania assumes a tangible form, will become millionaires. Meanwhile the sensation continues, and with every succeeding day the price of land continues to rise."

THE GOLD-MINING MANIA.

The Commercial Correspondent of the *Times of India* says:—

The Indian gold-mining mania shows no signs of cessation, so far as the London Stock Exchange is concerned, and whatever assistance can be afforded by brokers and jobbers to encourage it is certainly not wanting. One of the most influential of the circular writers connected with the Stock Exchange, hugs himself in that his anticipations though lately regarded "as savouring more of romance than reality are now" amply realised. "There is abundant testimony as to the extraordinary richness of the gold deposits which are only waiting the introduction of capital to develop." It would, we are assured, be "impossible for any report to be of a more favourable character than that of Mr. Brough Smyth," who "in consequence of his vast Australian experience, was specially engaged by the Indian Government to examine and report upon these properties." When the official documents are made public, Mr. William Abbott thinks the shareholders or the existing companies "will be proud of their position as pioneers of this great enterprise which cannot fail to benefit our Indian Empire, and galvanise our home markets into fresh life." The subscriptions for the capital of £100,000 of the Indian Glenrock Gold-Mining Company amounted to £700,000 from nearly 4,000 applicants. It is asserted that some large purchases have been made on behalf of capitalist, in Bombay, Calcutta, and Madras. "When," says the writer from whom I quoted above, "it is remembered that the merchants in those cities are possessed of enormous wealth, and that they are at all times quite ready to employ it in a speculative venture, it need not be a matter of surprise if these shares, and those of the South Indian Gold Company should advance to a very high price."

There seems to be very little cessation of the Indian gold-mining mania. A good deal of dissatisfaction has been expressed this week at the manner in which the allotment of the shares of the Glenrock Gold-mining Company was made; and it is said that some applicants for shares received more than others in proportion, and some received no allotment at all. An advertisement appears in the London daily newspapers inviting disappointed applicants to take united action for redress. But while it is only natural that some vexation should be felt, the allotment of shares is matter entirely within the discretion of the directors, and in the present instance there is no need to suppose that favouritism or undue influence was exercised. The business of the directors of a new company is to place the share into the hands of a strong and stable body of *bonâ fide* investors, and if, in the endeavour to weed out the professional speculators who only seek allotments to sell immediately at a premium, an occasional mistake is made, the general public will recognise and make allowance for the situation. The prospectus of yet another company has been issued this week. "The Gold Company of Southern India" has a nominal capital of £100,000 in 100,000 shares of £1 each; and its stated objects are, to purchase, hire, lease, or otherwise acquire mines and mineral properties, lands, or hereditaments, in India and elsewhere, which may be deemed necessary or advisable for the purposes of the company. No promotion money, bonus, or founder's share of any kind are to be paid, and it is said that "this company starting unfettered by contracts and unburdened with promotion money, the directors believe that, with a careful selection of properties, a future equal to that of the most successful companies is before it."

GOLD MINING IN WYNAAD.

INDIA was long reputed to be *par excellence* a country where wealth abounded. This reputation was made by travellers who visited the country some centuries back, and all those who wrote about India, previous to the present century, have invariably extolled the country for its wealth. In recent years a notion has become prevalent that India is a poverty-stricken country and that the wealth so much spoken of in former times was the creation of the poet's fancies. But Mr. Brough Smythe's exhaustive report on the gold fields of Wynaad leaves little room to doubt that the untold wealth of former days was not fiction, but a plain reality. It has been ascertained after careful investigation that of all known gold-bearing tracts none is comparable to the Wynaad for its extent and productiveness. These mines which were worked long before the Christain era appeared exhausted. But, in reality, the richest veins yet remain untouched. It is now generally accepted that, whereas the cheaper metals which are lightest are found close to the surface of the earth, the more precious ones which are heavier are found lower. The old native system of working the gold mines consisted in sinking shafts of which a very large number are now to be found all over the Wynaad. This is too expensive a method for deep mining and, therefore, tunnelling is required. The prospects of a Gold Mining Company are so far very good, but Mr. Brough Smythe fears that the first enterprises may be unsuccessful for want of skilful management. That the public entertain a very high opinion of the Wynaad mines may be inferred from the fact that seven times the amount of money required to start the Glenrock Gold Mining Company was tendered as soon as the prospectus was issued in London. This company has a capital of £100,000. The Wynaad is not the only place in Southern India where gold is available. This precious metal is also to be found near Kolar in the Mysore territory and in various parts of the North Arcot district. Considering the abundance of gold and of other valuable metals in many parts of this presidency, Government have taken a step in the right direction in notifying that, in future, all puttahs granted for waste lands shall contain a clause reserving to the Government the mining rights to the land. Referring to the production of the Wynaad Gold Mines Mr. Smythe says:—

'Tippoo Sultan procured large quantities of gold from some source and was possessed of great wealth. It is stated in *Maxwell's Life of Wellington* that amongst other conditions, exacted from Tippoo by Lord Cornwallis, he was to pay three crores and thirty lakhs of rupees in gold mohurs, pagodas and bullion: equal to nearly £3,300,000. On one occasion Tippoo sent thirty eight camel loads of money to Scindiah with the hope of securing him as an ally; and from the estimate of treasure and property taken at Seringapatam in 1799 there appear two items that clearly show to what extent the Sultan, in a comparatively short space of time and notwithstanding very heavy demands on his treasury, had been able to accumulate wealth. Of specie there was 16,740,350 Star Pagodas, and of jewels, gold and silver bullion, 25,000,000 Star Pagodas. His throne was sold unbroken for about £2,500, the gold not included in the purchase producing nearly 25,000. These facts and the knowledge we have of the enormous costs incurred by this Prince in supporting armies, constructing forts, and in procuring munitions of war and stores, sufficiently support the conclusion that he must have had ready means of procuring gold; but whether to any large extent from the mines of Southern India can only be conjectured.'

One fact not generally known about gold is that it is not usually pure in its native state. The Wynaad gold seems to be largely mixed with silver. In some samples forwarded by Mr. Smythe to Melbourne gold and silver were alloyed in the proportion of 57 to 43. The general average however seems to be 90 to 10.—*Madras Standard.*

FORESTRY.

THE FOREST SCHOOL.

STEPS are at last being taken to utilize the forest school at Dehra Doon, by the selection of young native gentlemen of good position and education to be admitted as probationers in the Forest Department. A resolution of the Government of India, containing the terms and regulations under which such appointments may be made, has been forwarded to all Commissioners of divisions, with instructions to make known its conditions amongst the native gentlemen of position in their respective divisions. The Forest Department is divided into three great branches, *viz.*, first, officers of the controlling staff in charge of forest divisions; second, officers of the executive staff in charge of forest ranges; third, officers of the protective staff in charge of beats. Promotion may take place within each grade, and also from one branch to another. The controlling staff is mainly recruited at present by the appointment of officers who have received a professional education in Europe, under the arrangements made for that purpose by the Secretary of State; but henceforth the sons of native gentlemen and other well-educated natives of India may obtain access to the controlling branch of the Forest service by two modes: either by passing the entrance examination at the India Office, and going through the prescribed course of professional education in Europe; or by obtaining admission to the executive staff, and afterwards earning their promotion to the controlling staff by distinguished service as executive officers. The central forest school has, therefore, been established, chiefly to make it easy for the sons of native gentlemen, and of youths of other classes who have received a good education, to acquire, within a comparatively short time, that amount of practical skill and theoretical knowledge which constitutes the professional training necessary for the executive staff. No apprentices will, as a rule, be received at

the forest school, who have not proved their fitness for forest work by service in the subordinate staff of the department during a period of not less than six months. The Governor-General in Council states that "A staff of trustworthy and efficient forest rangers is the first condition of effective local forest administration, and the chief object of the forest school at present is the training of such a class of officers. In the course of their service, forest rangers will learn by actual experience that *honesty is enforced and rewarded, and that without honesty and probity, efficiency is impossible*. This plan must, however, be aided by professional education. It may be urged that probity and professional skill are two things apart, which have no necessary connection. But professional education will have this advantage, that it will increase a feeling of self-respect." The italics are ours, but the sentiment thus expressed is, indeed, excellent, and its expression here only excites surprise in so far as it might be assumed without saying that Government has a liking for honesty in all branches of its service, and not merely in the gay greenwood.—*Pioneer*.

WOODLAND IN DIFFERENT COUNTRIES.

THE proportion which the woodland bears to the whole area of each country in Europe is said in the *Statistical Atlas* of André and Peschel to be somewhat as follows:—

In Sweden	Woodland occupies	39 per cent.
„ Russia	„	31 „
„ Austria and Hungary	„	29 „
„ Germany	„	25·5 „
„ Switzerland	„	19 „
„ Greece	„	18 (?) „
„ France	„	17 „
„ Italy	„	16·9 „
„ Belgium	„	15 „
„ Spain	„	8·9 „
„ Portugal	„	7 „
„ Holland	„	7 „
„ Denmark	„	5 „
„ Great Britain	„	2·4 „

These figures can only be taken as approximately correct; but even if there should be considerable errors in some of them, it is particularly noteworthy that Great Britain has such a small percentage of woodlands. Those who only look on the surface of things tell us that Great Britain is over-wooded at the present moment, and some go so far as to say that to this cause is to be ascribed the excessive rainfall, and consequent bad seasons, from which the country has suffered so much in the past few years. A greater fallacy could not be promulgated. According to such theorists every country in Europe ought to have from double to sixteen times as much rainfall as Great Britain! The fact is, the moistness of our climate arises chiefly, if not altogether, from natural causes over which man has no control, and upon which the present wooded state of the country can have at the most but the slightest modicum of influence. However, there are many parts of Great Britain and Ireland, the latter particularly, in which the *want* of woodlands seriously affects the prosperity of the inhabitants, and the miserable crops they laboriously try to cultivate. The want of trees, and a proportionate breadth of woodlands, to shelter crops and stock from the cold wet blast, is the greatest evil which the farmer and cottager has to contend with in far too many parts of our country. The agriculturist strives in vain against the combined evils arising from exposure to wind and rain, unless his crops are protected and matured by the ameliorating influences of trees in judiciously laid-out plantations. Examples of the beneficial effects of plantations are to be seen on every progressive estate in the country; although on far too many properties are seen the storm-swept, stunted crops, and starved, lean-looking stock, which are the natural result of the want of woodlands. Bleak wastes and hungry moorlands of the most worthless nature, have been transformed in a few years into rich pastures and smiling fields of waving corn, by the genial protection given to them by a well-arranged system of plantations. Thorough drainage and judicious planting are the two great factors in land improvement, in such a variable climate as we possess. Ten times the amount of woodlands which we now possess would not prejudicially influence our climate, but, on the contrary, they would add immensely to the general welfare of the community, if judiciously planted in those parts of the country where their presence is most wanted, or where their produce can be most profitably turned to account.—*Journal of Forestry*.

AMERICAN FORESTS.

FOR some years the attention of Americans has been forcibly drawn to the rapidly diminishing supply of produce from the indigenous forests of that vast continent, and which at a very recent period were popularly considered to be inexhaustible. Nor has that attention been given a day too soon to this most important factor in the future welfare of the United States and Canada. The axe of the lumberman is plied with injudicious vigour in the sweeping away of the forests, but the fresh settlers in forest tracts are also proverbially wasteful and destructive of the forestal wealth around their homesteads. Their chief object is how to get rid of the timber with the least trouble and cost, so as to grow corn in its stead with which to supply the markets of the world. This is undoubtedly a laudable object, but when another important necessity in the wants of man is utterly wasted in the process, and the climatic influences dangerously tampered with, it behoves the Government of the country to take effective measures for the prevention of this enormous waste of the economic products of the land. All over North America the same evil has hitherto prevailed, almost unchecked by any laws, or if laws have been promulgated they have been systematically ignored; sometimes through their impracticable nature, but more often from the want of a direct superintendence by the Government of the country, and the employment of duly qualified officers to see the laws obeyed, and the spirit of their enactments carried into effect.

However, there is a prospect of better regulations being initiated ere long for the preservation of the forests of the United States. Public opinion is being roused on all sides to the urgent necessity of immediate action being taken for the protection and proper management of the extensive and valuable-timbered areas which still remain of the vast forest tracts of earlier times. Many earnest workers are in the field, each striving to enlighten the public upon the vast importance of the subject, in a national or economic point of view, or treating of some special point, deemed of primary importance for carrying out a well-regulated system of State forest management. Among others, Professor Sargent, Dr. Warder, and Dr. Hough have all done eminent service to their country. Of the more recent writers, Mr. S. V. Dorien displays a zeal that is most commendable. In a pamphlet recently issued by him at New York on the "Protection of Forests" he treats in an able manner of the *necessity* for *at once* protecting what remains of the noble primeval forests of America. He goes over the many well-known instances of the ruinous effects which have been produced in different European countries by the wasteful and ruthless destructions of their forests, and conclusively proves that America is in imminent peril of suffering seriously in wealth and prosperity from the same cause. He rightly argues that "the forest is a part of universal nature. We cannot do without it. As water is a necessary constituent of our earth, so is the forest. It was handed down to us by our ancestors, and must be transmitted to your descendants. If we acknowledge the indispensableness of its existence, the duty of its preservation is but a necessary consequence; nor can it be doubted that if individual owners neglect the care due to the woods, the representatives of the body politic are not only entitled but obliged to interfere." With these evils so clearly brought before them the people of America cannot fail to see the danger ahead, and to strenuously insist upon measures being at once adopted for the conservation and economic management of their indispensable forests.—*Journal of Forestry*.

GARDEN.

STRAWBERRY CULTURE.

IN an essay on the above subject read before the Indiana Horticultural Society, Mr. Ohmer said:—

For field culture, I plough and harrow as for any other crops. I plant in rows three feet apart, and twenty-four inches apart in the row. I cultivate with a one-horse cultivator that will not go too deep, nor throw up ridges, then use hoes to cultivate in the rows. I allow the runners to take root in the rows, making what is called a matt ed row. The hill system can be practiced in field culture, as well as in a garden, which is done by many of our best cultivators, in which case, plant closer, say fifteen inches apart in the rows, and cut off all the runners as directed for garden culture; in either case, it is absolutely necessary to keep the ground free from grass or weeds. Cultivated in matted rows, your cultivator should be narrowed, so that when done the matted rows would be about twenty to twenty-four inches wide, leaving an uncovered space of about one foot wide, so as to enable the pickers to get through to gather young fruit without tramping on them. I mulch in field as described for garden, one inch deep with clean straw. I don't mean one inch solid but loose, merely to cover the plants from sight, which is all that is necessary. In spring I do not disturb the straw, but let it lay, the plants will come up through nicely. I do nothing to my strawberry field in the way of cultivation in spring, except if they are too weedy, to cut (not pull up) down the weeds. After the berries have been gathered, I cultivate thoroughly between the rows, leaving from six to ten inches wide of plants

which cultivation must be repeated as was done the season previous. Two crops are all I think profitable in this manner on culture, as new plantations can be put out at less expense and produce more and better fruit than an old bed. One hundred and seventy-five bushels per acre is the most I ever gathered grown in this manner, and these were Wilson's. This amount can be largely increased if what has been said of the Crescent is all true.

TEA.

THE tea industry seems to be on the eve of a crisis. The last number of a contemporary devoted to that industry, contains a review of the operations of several companies, and if its conclusions are correct—and we see no reason to doubt them—this crisis is being brought on by bad management, either on the gardens or in the agencies' chambers. For instance, we find one company the making of whose tea has cost as follows:—1877, 11 annas 11 pies per lb; 1878, 12 annas 10½ pies per lb.; and in 1879, 13 annas 9¼ pies per lb.; while the article sold as follows:—1877, 13 annas 3 pies; 1878, 14 annas 2 pies; 1879, 10 annas 10½ pies per lb.

The selling price was unusually low last year, but this steady increase in cost is inexcusable; some gardens, similarly situated, turn out their tea for 9½ annas. Another instance is mentioned of a company with a capital of 9½ lakhs, earning a gross dividend equal to Rs. 19 more than was paid for "Directors' and Auditor's fees and commission to Secretaries and Managers." We suspect the Managers did not get much of this lump sum, and we do not see that they deserved much, as their out-turn was only 153lbs. per acre, a result of which any manager should feel ashamed. If we are not to lose our tea industry altogether, we must contrive to conduct it on such principles as are consistent with ordinary prudence and common-sense. The habit of putting the "sisters, cousins and aunts" of managing agents and directors in charge of the garden, must give place to the more sensible one of putting properly qualified men in charge, and Government must be induced to remove the terrible incubus of Act VII. of 1873 (B.C.) which sits on the industry like an old man of the sea.

CONCERNING tea prospects, Messrs. Moran and Company have the following remarks in their circular of 21st ultimo: "We regret that again this year we are not in possession of sufficient data on which to base an estimate of the coming crop. It is evident, however, that the increase will be very considerable. Regarding last year's crop we calculate, from latest advices from London and from the Calcutta Custom House returns, that the total out-turn of season 1879 was about 40,000,000 lbs., of which about 39,000,000 lbs. were exported. As this quantity was in excess of the demand in London, stocks there have enlarged, and this, together with the expected increase in production, must induce a lower range of prices, and planters will find it to their advantage to make up for this by turning out a better quality of tea. We are glad to see signs of this improvement in the samples which have been sent down of this year's make.

"Weather reports during the last fortnight are not very favorable. Sylhet has been visited with heavy storms, accompanied by partial floods, which have done considerable damage to some estates. Hailstorms are reported from Cachar, but gardens appear to have suffered but little harm. In Assam, planters in Dibrooghur are well ahead of their estimates, but from other parts of this district reports are not so promising. Darjeeling gardens are doing well, but rain is wanted in the Dooars, as also in Chittagong and Hazaribagh."

INDIAN TEA.

From a Tea Traveller's Point of View.

NOTICING in a recent number of the *Mail*, some account of the way in which Indian tea sales are conducted in Mincing-lane, it occurs to me that those of your readers who, from pecuniary or patriotic motives are interested in the subject, may like to learn something of the reception of the tea by the retailers when presented for their approval by the humble agency of the class of which I am a member. The grocers are the real masters of the situation, and it is only through their co-operation that Indian teas can be successfully brought into general use; therefore, if the trade is to be expanded, it must be by making tea such as will gratify the grocer. It follows, then, that it will be more profitable for the tea planter to study the taste of the smallest and most illiterate retailer rather than the cultivated palate of the most dignified and financially potent "rooster" of the Commercial Sale-rooms. For the former can extend the drinking of Indian tea to the whole of the consumers who deal with him, while the latter has no direct power to increase the consumption, and so that he makes his profit when the tea passes through this hands, cares little whether the public be pleased or poisoned.

Unfortunately, we travellers have to deal with clients amongst whom are many knowing little of what constitutes the best tea. Uneducated in the trade, the only criterion of value is the individual fancy. Unlike the broker, the commercial traveller has to take into account temperament as much as tea. The traveller is not perched on a rostrum, surrounded by eager buyers, but has often to trudge many weary miles to effect a sale, and then must find sufficient energy to convince a probably ignorant client that a certain kind of tea is the best, for which labour, in the end, he very often gets more kicks than half per cents. Dealing with a fictitious estimation of value, proof is not possible. Moreover, the question of the value of a tea depends, in many cases, upon the traveller who offers it, and not upon its intrinsic merit. Should you be on terms of intimacy with your customer; above all, should you be regarded with a favourable eye by your customer's wife, or should you display judicious solicitude anent the teething of his youngest, then the way is easy, and whatever you offer will be cheap and good, and whatever is offered by anyone, not thus happily circumstanced in the family affections, will be dear. This class of buyer is, I take it, the salvation of bad tea growers, for by no other means could their tea get into consumption, unless offered at prices which would not be remunerative. The pressure of competition is, however, rapidly remedying this state of affairs, and there is now an intelligent attention given to tea by the retail trade, formerly unknown. Many grocers test the samples submitted to them with much more care than the "roosters," whose lives are made burthensome by the number of small lots they must daily taste, and whose only hope of safety—in the hurried liquoring, and consequent unsafe buying—lies in the diversity of tastes, and in the ignorance of their customers, allied with the confidence with which their "selections" are received by the letter. First and second water; how the tea takes the milk; how it blends with China tea; these are all details carefully studied by the educated retailer.

It is only the opinions of the latter class which can be of value to the producer of Indian tea. It would be casting pearls before swine to set about manufacturing tea to please the first described kind of buyers because their pleasure in the matter is an unknown quantity at the mercy of every traveller who ingratiates himself into favour, not by the cheapness of his samples, but by his own dearness to his client. I may mention, with regard to Indian tea, that I have usually found it receive most attention from these retailers who, in their knowledge of tea and the art of tea-mixing, are furthest advanced.

The great majority of grocers use India to back up and strengthen China tea, and the minority in order to flavour it; but, except in Ireland, only a fractional number make Indian tea the staple of their canisters. Neither of these purposes, I opine, are what the interested lover of Indian tea, or the disinterested lover of his country, would wish to see. They look forward to the day when the British Empire shall be self-supporting in the matter of tea—when, metaphorically speaking, we shall sit under our own tea shrubs and draw refreshment from the grateful leaves. They do not want our own tea to be used merely as a prop to support the weakness of the China. But at present this is practically the use to which it is put, and there are some good reasons, which I will mention why this is so.

With great care in selecting, and in graduating their customers to the change, some grocers have got so far as to make their mixtures half China and half Indian, or even with a preponderance of the latter. But in such a case the task of selecting and *matching* the Indian teas, the smallness of the parcels when found, and the consequent need of more frequent and heavy tastings make the work one which, if the ordinary run of grocers were to attempt it, would usually result before long in driving away many of their customers; because having other work to attend to, they would be compelled to buy in the usual haphazard way, without tasting many samples. With Indian tea this system would not answer. In China tea, on the other hand, price is some guide as to quality and sort, but in Indian it is next to none, and the produce of different gardens, sold in Mincing-lane at the same price, would make or mar the retailer according to the chance of his choice. With China tea there is no such peril in its use, and consequently it is felt to be safer to "go on" a large quantity of it in a mix and only throw in a small portion of Assam or Darjeeling to give strength or flavour. The average admixture is about one pound to six of China tea. Often in urging a man to buy some specially *useful* parcel of Indian tea, and to put a larger proportion in his mixtures I have been met by the reply, "What is the use of altering my mix, I won't be able to follow it." This illustrates what I have said, that the enormous diversity in Indian tea makes it unsafe for the retailer to use it extensively, unless he gives to the subject a disproportionate part of his time. Variety is pleasing no doubt but in Indian tea it appears to have been over-studied, and if the planter would save the labour he bestows in dividing the produce of his precious acres into so many distinctive sorts, from flowery Pekoe to earth-flavoured siftings, and lump the whole together—giving only so much attention to appearance as that it be not a "straggly" leaf,

fairly even, not too brown or too large. In fact, somewhere between a China Saryune and Moning—and then concentrated all his attention upon the liquor, he would probably be a step nearer ousting his Chinese rival than in preparing teas which are usually either too good—at any rate, too strong—or too bad to be taken without a pinch of Congou. One of the chief reasons why China tea continues to keep in favour, despite some of the more brilliant qualities of its rival, is probably owing to the fact that it possesses a roundness and mellowness in liquor which for the most part is wanting in Indian tea. This causes it to thicken and assimilate with milk. Pungent Indian teas fetch very high prices because the idea is that they please prudent housewives by giving to the second brewing additional strength. Indeed it is this second cup which is constantly in the mind of the grocer in his use of Indian tea. But I am inclined to think that these pungent teas simply spoil both first and second cup by their disagreement with the milk. As ground for this opinion, I have noticed that among the most careful blenders of tea the demand is less now for pungency and more for thickness, fullness, or roundness of liquor. In short, as the end of all tea is its drinking and as ninety-nine in every hundred people use milk in doing so, it follows that the action of the latter ought to be observed most critically. The majority of Indian teas, as I have said, do not assimilate well with milk, becoming herby, or throwing off a foreign weedy flavour, while China sorts, except the most worthless, all improve under its influence, and please the average tea-drinker. The three things which seem most required to popularise Indian tea are greater uniformity of quality in leaf and liquor; breaks as large as China teas—and the one of course almost necessarily entails the other—and last but most important, the utmost care in securing a *general tone of thick mellowness*, even at the expense of the more prominent qualities, such as pungency, distinct flavours, and the much over-estimated leaf. In small quantities such attributes may ensure Indian tea a higher price, but as supplies become larger it will end in its general depreciation, for it is thereby debarred from universal estimation, because, regarded as a drink, it is not palatable. A comparison of the present state of the China and Indian tea markets points this moral, for the inflation of the one appears to be no help to the other, and Indian teas could never be bought cheaper than now, simply, as I believe, because, beyond a certain quantity, they are found to be unsuitable owing to the present mode of preparation.—*Home and Colonial Mail.*

J. A. J.

THE CHINA TEA TRADE OF 1879.

IN their annual review of the tea trade in China, Messrs. Little and Co., of Shanghai say:—

The year under review is remarkable as being, apparently, the turning point in the last period of the alternating series of years of arrested and of excessive production, and of overtaking consumption which culminated in the unexpectedly moderate crop of the past season.

Ever since the year 1871 when the production of Congou in China jumped from 150,000,000 lbs. in the previous year up to 172,000,000, and since the year 1872 when Green Tea rose from 29,000,000 to 34,000,000 lbs., the home markets have been constantly furnished with an annually increasing supply from China contemporaneously with rapidly augmenting yields from other competitive countries, chiefly India and Japan. The result has been that, in the face of a fast increasing consumption in all quarters, a decline in value has been steadily proceeding throughout that period, until at length a level was reached at which tea could no longer be packed for the Western markets without heavy loss; although prices in China which, with some disturbing fluctuations, had been tending persistently downwards, never fell so low as they did in London and New York, yet the fall was sufficient to render the picking of leaf in many of the less favourite districts unprofitable, and so fresh plantations meanwhile constantly coming on retain the yield at last at a nearly stationary figure. The overtaking consumption was thus enabled to come up with the production, and an enormous and sudden advance in prices in all the consuming centres re-acted upon China but too late, fortunately, to render an increased supply possible this season.

We have thus just reached the end of one series of increasing, followed by stationary, production, and are about re-entering another. We shall start this coming season with a full supply, which will continue increasing year by year until we again send forward so much tea as to bring about the inevitable collapse by which the production will be again temporarily arrested.

It must never be forgotten in endeavouring to form an estimate of the probable yield (as a basis of probable value) of the tea-plant in China, that relatively only a small portion of the total harvest is gathered for the purposes of export. In a country in which no collection of statistics is attempted, and in which the merchants keen as they are rarely look beyond their own immediate circle and despise rather than attempt to copy our Western enthusiasm for figures, it is impossible to estimate with any degree of certainty what is the relative proportion of home consumption and export, but as a guide to friends at a distance who may be willing to make the attempt, we will enumerate a few facts as data upon which to form a conclusion. We may premise in regard to the third fact that we have (after the devastation of the Green Tea districts by the rebellion of 1860-64) never known the leaf so scarce in the country that the poorer portion of the population were reduced to hot water as their beverage, but as the tea districts are now, and have been for a long period free from disturbance, and as they are outside the area of the famine which has recently depopulated the north-western portion of the empire, there is but scant chance of the recurrence of such a contingency in the immediate future. The facts are these:—

1.—The population of China and dependencies is 250,000,000, to 300,000,000.

2.—The population of Western tea-consuming countries (England and Colonies, Russia and United States of America) is 160,000,000.

3.—The beverage morning, noon, and night, of every Chinaman who can afford it is tea (wine being only drunk exceptionally and cold water never).

4.—In Western tea-drinking countries, apart from alcoholic drinks, coffee takes an equal place in the consumption.

5.—The area of unoccupied land suitable for teaplanting is practically unlimited: of the tea already planted much remains unpicked every year when the price of common Congou is too low to be remunerative.

6.—The cost of picking, firing, packing, inland freight and duty, export duty and freight and charges to London or New York is not less than 8*d.* per lb. upon tea sold at home; at this figure nothing is left for the producer—or, seeing that he picks no leaf that he cannot sell—the price paid to him (never less than 8*d.* per lb.) for the raw leaf, is all lost between the native packer and the foreign importer.

From this it will be seen that there is an *unlimited* reserve of tea for export in the supply retained for native use, provided the price foreign shippers are willing to pay is sufficiently high to pay the extra charges for packing and duty over and above the lower expense of preparation for native use. In the season just past prices until October (six months after the bulk of the crop was picked), ruled so low that native buyers were able to lay in large stocks all over the eighteen provinces; when the rise came, the tea had been already so far distributed that the getting it again together in quantity to make chops for export was impracticable. Had the rise come three months earlier the export would have been enormous. As it was, our first crop was a very heavy one, but it realised such low figures that a large proportion of the tea men had no funds left wherewith to return to the packing of a second and third crop, which was hence freely diverted to native use. We thus have this paradox to deal with each season: either low prices at the beginning, short yield and probable large profits, the expectation of which would seem to justify fair rates being paid, such as competition to buy ensures; or, fair prices at the beginning, a heavy subsequent yield, and almost certain loss in prospect, such as should lead to low prices and absence of competition. How it has been met hitherto we all know. Is it likely that it will be met with more sagacity in the future?

The recovery in trade in Great Britain came too late to make much impression on the consumption of tea in 1879, notwithstanding which the deliveries in London show an increase of four million pounds on the previous year's, leaving the stock of Black Tea in a much improved position.

COFFEE.

THE prospects of coffee in Ceylon appear to be anything but favourable. Considering the amount of capital invested in that industry, the outturn seems very small. From the commencement of the season, on 1st October 1879 to 5th April 1880, the total exports have amounted to 429,525 cwts, as against 535,596 cwts for the corresponding period of last year, showing a decline of 20 per cent., and we are sorry to see that the proprietors are not taking the proper means to recover themselves. We note that they are discharging their assistants right and left, and from a correspondent in Ceylon we learn that 400 planters are now in the island idle. It may be, however, that the proprietors cannot help themselves, and that the coffee industry is on the eve of a crisis which will result in the ruin of a large number of proprietors, and possibly afterwards in a more healthy state of the industry. In 1864-66 the tea industry passed through such a crisis, and is perhaps not far from another. After the former, many errors arising from ignorance were corrected. It had been the habit to look on the possible profit as something over, and never to be under, 100 per cent., and all outlay, including managers' salaries, was based on this assumption. Under this delusion vast areas of land were brought under cultivation in the most perfunctory manner, and it was subsequently found that the companies had not sufficient funds to cultivate these tracts until they came into bearing. Consequently all concerns so conducted failed, and were taken over by new proprietaries at prices—in most cases—considerably under their real value. With the coffee industry we imagine the cause must be sought elsewhere. We apprehend it arises from the fact that few of the companies or proprietors are at liberty to sell their produce in open market, and the industry will never be healthy until this is changed. A

garden, we will say, is mortgaged to a firm in Colombo or in London; all the produce must therefore go through that firm, and such a state of things results in what are known in America as "rings" which are fatal to free trade. With ordinary cultivation, we do not see why coffee growing should not pay. The expenses should not be so much per acre, while the value of the gross produce ought to be as high as with tea; but until the owner can arrange to sell his crop in the open market, he need never expect to reap the fruits of his labour. A large commission sticks somehow to the fingers of all through whose hands his crop passes, and he will never get rid of these ruinous commissions till he is able to place himself in direct communication with the open market.

MESSRS. KOLFF AND COMPANY of Batavia, have published an interesting pamphlet entitled "Historical and statistical notes on the production and consumption of Coffee," by N. P. Vander Berg, LL.D. (the President of the Java Bank), translated into English by Mr. G. G. Batten. In a short sketch, of about 90 pages, the author reviews the gradual increasing or decreasing crops of the producing countries, and from data, carefully collected and sifted, estimates the total annual amount of the fragrant bean offered for sale in the whole world at 490,000,000 of killos, or 482,280 tons; whilst the consumption, calculated in the same careful manner, is put down at 489,070,000 killos., or 481,370 tons, leaving a small balance of 910 tons to meet eventualities. It would appear, according to these statistics, that the Dutch are the greatest consumers of coffee, 8·12 killos. per head; next the Belgians, 4·14, then the Norwegian, 3,96, whilst the French consume only 1·38 killos. a head, the English 0·45, the Russians 0·10—or in other figures the Dutch consume 17¾lb against the Frenchman's 3lb., the Englishman's 1lb., and the Russian's 3½ ounces.

COFFEE CROPS, PRICES, AND WEATHER.

THERE is at the present moment much cause for anxious thought and speculation as to the course of the home coffee market, and the outcome of the present season on the ensuing crop. We have so frequently directed attention to the causes, apart from the extent of our own shipments, influencing prices in Europe, that we need not repeat them. We see our lessened exports reaching home to realise lower prices, and the moral of this is a strengthening of the oft repeated argument in favor of selling upon the spot. Considerable sales of plantation coffee were made during the month of March at from Rs. 54 to Rs. 56, free on board, but not a few preferred shipping their crops at the risk of the market, rather than accept Rs. 55. Since they refused that price, the home market has declined seven shillings with no early prospect of a revival. That prices at home will recover when the existing heavy stocks are reduced we do not doubt, but before that can take place, a good deal of produce, will be sold at a sacrifice that might have been avoided.

Just now the outlook is not what was anticipated a month or two ago with coffee at upwards of 100s. in the London market, and a favourable weather forecast promising as some sanguine spirits anticipated, a large, if not a bumper crop. But we are already realising the uncertainty of everything dependent on seasons, for having passed through a third of the month of April, which was to realise our fondest hopes, we are compelled by the strange freaks of weather, to modify our calculation and bring down our anticipations to moderately paying crops, which is admittedly all we dare to hope for. Leaf disease the once dreaded enemy of the coffee plant, has, thanks to some atmospheric influence, diminished to small proportions; trees which in former years wore a poor and attenuated appearance, are now densely loaded with bearing wood and healthy foliage, and are willing and ready to do their part in regard to a plentiful show of blossom, but that the adverse season has hitherto forbidden it, and even at this critical moment holds every attempt in abeyance waiting only the advent of a warm and forcing sun.

The break of the "little monsoon" has been attended by indications rarely encountered at such a time. Nearly all the rainfall has taken place amidst a dead calm, being rarely accompanied by wind: moreover, such wind as blew fitfully and faintly, has been from all points of the compass, and this added to the unusual abundance of electric phenomena, leads to the belief that the "little monsoon" has come upon us by means of the centre of a mild cyclone. The absence of wind explains the slight extent to which the weather has rescued interior where it appears to have been scarcely felt, with every probability that it will exercise no pre-judicial influence on the blossom.—*Ceylon Times.*

LIBERIAN COFFEE.

THE advantages of growing Liberian coffee, over the ordinary descriptions, are so many that it is very satisfactory to find it has been successfully cultivated in this province. A writer in the *Ceylon Observer* says that an estate of 20 or 30 acres of Liberian coffee well looked after would yield as much as one with 200 or 300 acres of coffee Arabica or Ceylon coffee. The Liberian coffee berries are big as plums and the unpruned coffee has no leaf disease. The flavour of the Liberian description is said to exceed in excellence the best description of Arabian coffee, so that high prices may be expected for the crop. It is said to grow equally well in estates at Ceylon in the neighbourhood of the sea and in those at a considerable distance from it. The first crop is generally only a few berries but the tree goes on increasing until it becomes capable of yielding 20, pounds of berries. Some old trees have yielded as much as 24 pounds each. It grows to a height of between 20 and 30 feet. Some cultivators top their trees, other let them grow *ad libitum.* Trees that are topped are more conveniently picked, and other things being equal, give a large crop, whilst when the trees are tall they are frequently injured by the climbers picking the berries, as the trees ripen their crops and blossom for the next year at the same time, and much blossom and young fruit is rubbed off unless great care is used; whereas the low trees can be picked whilst standing on the ground. A Ceylon coffee planter who went to Liberia says he has seen trees forty years old flourishing in all the vigour and verdure of young and bending down under their weight of berries. The Liberian coffee plant is not a shrub but a handsome forest tree. Some of the old trees when cut down shoot up rapidly and more vigorously than when first planted from the seed. Mr. W. Bull, of King's-road, Chelsea London, supplies established plants of this Liberian coffee which can be safely despatched by the direct steamers from Glasgow to Rangoon in one of Mr Bull's patent plant cases many of which have been sent to India. We are glad to hear good accounts of the trees planted in the Agri-Horticultural gardens in Rangoon by the enterprising Superintendent, Mr. J. C. Harding, as well as those in the Soldier's Gardens Cantonment by the indefatigable Colonel Hawkes. The Forest Department should have a plantation of these trees at Magayee and at Tonghoo. It would pay better than the Cinchona, which from all accounts is not a success.

Even if we cannot become a coffee exporting country, which under the present illiberal system of giving land to planters is not probable, we might surely make ourselves independent of imports from other countries. The price of coffee at present in Rangoon is about Re. 1-8 per viss or not much under a shilling per pound. If every person with a garden at or near Rangoon grew half a dozen of these trees, they might render themselves independent of bazaar supplies of this refreshing drink whilst others whose land was more extensive could not do better than try an acre or two with Liberian coffee.—*Rangoon Gazette.*

COFFEE CULTURE IN GUADELOUPE.

AFTER sugar—the principal agent in the prosperity of Guadeloupe—coffee takes the first rank among the secondary products. It was formerly the first among our staples. Without occupying ourselves now with the causes which led to the abandonment in too many parts of the colony of this culture, so flourishing before 1789, let us take as a point of departure the year 1815, the date at which France retook possession of the island, which had been subjected for the second time since 1810 to the domination of Britain.

In 1816 the coffee crop produced no more than 284,135 kilog., but starting from the succeeding year and on to 1830, it assumed considerable proportions. Guadeloupe during this period of 15 years exported 15, 6 ,050 kilog. of this valuable berry, being a mean annual export of 1,019,6.2 kilog.

2nd Period. 1831 to 1845—During this period the cane cultivation greatly extended. The handsome prices which sugar then obtained in the metropolitan markets, whilst fortifying the courage of the sugar planters, strongly excited the cupidity of the owners of the coffee plantations, who saw with a jealous eye, or rather with a greedy eye, the growing importance of the sugar estates of the colony. Without a thought to the deceptions which the future might be preparing for them, they saw nothing but the splendours of the present, and, no wiser than the frog in the fable, substituted the sugarcane for the coffee trees on their properties.

Tout bourgeois peut batir comme le grand seigneur.—The export tables are the faithful reflex of what took place in this second period. The quantity of coffee exported diminished by half, and sugar shews a larger output. It is thus that instead of 15 millions, the colony exported no more than 8,613,631 kilog. of coffee at this period, being a mean annual export of 574,678 kilog. It is right to add that it was at this period that the coffee disease appeared and caused such grave anxiety among the planters.

During the *3rd Period,* from 1846 to 1860, the decrease in the coffee production was even more appreciable. It is true that about this time we had emancipation, whereupon the blacks located on those coffee estates which had not yet been converted into sugar plantations on account of their topographical situation, abandoned the heights to fix themselves on the sea coast, which had all their preference. The total exports at this period are not more than 3,863,720 kilog., giving a mean annual export of 214,267 kilog.

4th Period: 1861 to 1876.—Though in smaller proportion than at the first period, the exportation of coffee increased at this time by more than a million kilog. It was in effect 4,747,069 kilog., giving an annual mean of 316,477 kilog. We feel here that immigration has furnished hands to the coffee estates, and that the work of production has become more systematic.

The results of the three years, 1876, 1877, and 1878, confirm us in this opinion. During this short period the colony exported 1,332,895 kilog. of coffee, giving a mean of 444,276 kilog. per annum.

That coffee is destined to further extension by retaking at certain points excellently suited in soil and climate to its habits of growth, the place which it has ceded to the sugarcane, we are well assured. We know a

sugar estate which, under the intelligent direction of its new proprietor, has again become a *cafeière*. The revenue which the new culture gives yearly affords him no reason for regretting the change. His example we have no doubt, is one which will sooner or later be extensively followed.—*L'Echo de Guadeloupe.*

COFFEE IN BRAZIL.

Kern, Hayn & Co.'s Annual Market Report.

RIO DE JANEIRO, 1ST January 1880.

THE year just closed has to Brazil in most respects been an agreeable contrast to the previous one; while during the year 1878 prices for coffee as well as rates of exchange declined steadily almost during the entire year; the reverse was the case during 1879, consequently the country has witnessed an improvement in the export as well as in the import trade. The latter, especially, was, as far as we can judge, conducted on a sounder basis than during the previous year; a good deal of illegitimate competition fell to the ground by itself and the rising exchange of course favored importers very much.

COFFEE.—This article has again during the year under review presented most interesting features; whereas prices during the year 1878 declined $1,800 to $2,000 per 10 kilos for "Ordinary first" and 950 to $1,100 per 10 kilos, for "Good first," the year 1879 witnessed a still larger advance in prices, the difference between the lowest and highest point in price for the same two qualities being respectively $2,150 per 10 kilos, and $1,4 0 to $1,450 per 10 kilos., the lower grades, say "Good second" and "Ordinary second," presenting a still bigger price difference. In the f. o. b. cost the difference between the lowest and highest point is comparatively still larger than in currency prices, as will be seen from the beneath table which circumstance was called forward by fluctuations of exchange. It will be seen from same table that the lowest point in the f. o. b. cost was on the 23rd May, say a cost for "Ordinary-first" in the Channel of 47s 8d. to 49s 1d. per cwt. and a cost for "Good-first" in the United States of 1290 c to 18" 18c per lb., whereas the highest point was on 6th December (not counting 23rd December, when prices were nominal) with respective costs of 11s. 77d —74s 6d., and 17 71 c.—17 93 c., the difference between the lowest and highest point thus amounting to 27s. 3d —28s 5d. per cwt in the Channel and 4 75 c.—4 81 c. per lb. in the United States In 'Ordinary second" the difference between the extremes is as large as 8 s per cwt in the Channel and 6½c. per lb. in the United States, the lowest range of prices for this quality being at the beginning of the year and the highest on 6th December.

It is rather interesting to see the extraordinary difference between the extremes of stocks witnessed during the past year; the smallest stock was 200,000 bags on the 7th January, and the largest 403,000 bags on the 16th December, and it is rather characteristic that prices were about at their lowest point when the stock was smallest and about at their highest point when the stock was largest.

The quality of the 1879-1880 crop shows a crass contrast to that of the previous crop. It will be recollected that the 1878-1879 crop was inferior to what any previous Rio crop had presented, "superior" so to say not existing at all, and even "Good-first" being very sparingly represented, whereas a considerable quantity of the very lowest trash was on the market almost during the entire season;—the 1879-1880 crop, on the contrary, until lately offered so to say no "Ordinary-second" at all, and then only limited quantities, "Good-second" has been pretty scarce, and at times it even was difficult to obtain "Ordinary-first" alone.—The 1879-1880 crop show a good-sized bean and more cleanliness of the coffee than usually, under which circumstances we at the beginning of the season adhered to the hope that the selection during the present crop would be kept very strict, but we are sorry to say that several times with a rising market we have witnessed pretty slack selections.

The total export from Rio de Janeiro during the year 1879 amounted, as will be seen from the table below, to 206 827 tons against 167,210 tons in 1878 and 162,105 tons in 1877, thus showing the considerable increase of 39,087 tons on 1878 and of 44,222 tons on 1877, and it will be seen that almost the entire increase falls upon the United States. If however we compare the shipments of the last two years during the second semester only, we find that those of 1879 show a decrease against those of 1878 of 4,184 tons, so that the increase in the total shipments of 1879 against 1878 falls upon the first semester, same actually showing an increase of 43,221 tons; as will be seen from our report of 8th July, the shipments during the first semester of 1879 amounted to the heavy figure of 101,208 tons (1,734,994 bags), so that during the year 1879 the shipments were about equally divided between the first and second semester, a very rare case.

In our report of 8th July 1879 we stated that with regard to the extent of the 1879-1880 crop, most estimates then varied between 2,500,000 and 3,000,000 bags, and that according to our opinion it was likely to be nearer the latter than the former figure. Let us suppose it to have amounted to about 2,800,000 bags, in which case with the stocks on 1st of July 1879 of about 90,000 bags in Rio and of about 1,000,000 bags in the interior we would have an available quantity for shipment from 1st of July 1879 up to 30th June 1880 of about 3,900,000 bags, of which quantity about 1,800,000 bags were exported from 1st of July to 31st December 1879, so that with a probable export during the present semester of 1,600,000 to 1,600,000 bags, we would, on 1st of July prox., remain with a quantity of coffee left over 500,000 to 610,000 bags.

With regard to the 1880-1881 crop we have to state that the prospects for same are so favorable that at present there is reason to believe that a large crop might be expected, but it is not unlikely that the crop may be a late one; to name a figure with regard to the probable extent of the same is at this time of the year entirely impossible.

CACAO.

COCOA (OR CACAO) IN TRINIDAD AND IN CEYLON.

(*Communicated.*)

THE fellow creatures, and brother planters, of the author of the "wee bookie" on cocoa in Trinidad owe him thanks for communicating what has cost time, trouble, and money to obtain; though some of them may regret, that he should have gone so far, and brought back rather little.*

He tells us that the Trinidad planters reject for seed the small nibs at both ends of the pod; we shall probably follow this good example, when we are able to purchase it at a lower price than seed now commands, but in the mean time, as we are pretty certain to lose a large proportion of our plants, we must not throw away the chance of even the weak seeds it is planted in nurseries first, not more than "two-and-a-half inches deep," and afterwards transplanted. We have sown it in nurseries here and afterwards transplanted it to the field with the result of losing a large proportion of our plants extending in some unfortunate cases to saving none. We have found the plant resenting removal even to death, and at the best maintaining a protracted struggle to counteract the shock, especially, where it had to encounter dry weather.

* Our correspondent is a little hypercritical, and the following remarks of the author will explain the object he had in view:—"In that little cocoa pamphlet that was sent to you from England the other day, there are one or two mistakes in the printing, but the one specially to be noted is that the engravings where *stove* is printed for 'store.' I do not doubt but that some will think that the book is too small, but none would do so who have had any experience on a 'cocoa walk,' as it is a well-known thing that there is very little done in the way of cocoa cultivation, as it takes care of itself to a great extent. And so beyond giving a good ground work on the subject there was not the slightest use in raising questions that probably not one Ceylon planter out of a 1,000 would believe in, so having dispelled an idea common in Ceylon that cocoa requires washing, which process simply means *destruction* with regard to value, I intend to keep to myself the other peculiarities which I have learnt for my own private use, and time will prove who is right and which is the best principle. Just fancy my trying to persuade Ceylon planters to wait patiently for five years and not allow their trees to bear, or how could I press on a man that if he uses seeds from a tree of three years old, his produce will not be a good tree, or that without fail a tree should never be allowed to have more than three boughs at the start, and not four, and heaps of other things besides. If ever you should require more copies and would like a little more added, I will do so, but we will [illegible]. Cocoa is not the subject that coffee is for a book, and that I will maintain against all comers."—ED. C. O.

before it was fairly settled. We did not sow the seed two-and-a-half inches deep, not even one inch; yet we have lost largely from the force of growth being insufficient to extricate the seed from its bed. The stem comes up in the form of a bow, held firm at one end by the root, at the other by the seed; as it lengthens the curve narrows, the tension becomes too great for the delicate tissue, and it snaps asunder, leaving one-half of its length attached to the root, and the other to the seed; then if the midday sun should shine on it, while in this condition, for one hour, it is irretrievably lost. Therefore the seed should not be covered even one inch, and never with any substance that will become stiff under either wet or dry weather. The best coverings are coir dust, cinnamon scrapings, sawdust, or loose sand.

In Ceylon, a good deal of seed has been sown in bamboo joints, but the inside of such pots being of equal width from top to bottom, the ball of earth cannot be taken out entirely, and there is great danger of breaking it up, in splitting and removing the bamboo in pieces, therefore the plan if planting without removing the bamboo has been tried, but not found satisfactory. The taproot soon gets beyond the pot, but the taproot is not a feeder, the plant is starved, when the food contained in the pot is exhausted, and death ensues; merely because the roots are confined to a narrow space, and cannot spread, and forage the surrounding soil.

Sowing at stake will probably become the common practice in Ceylon, but this method has its dangers, as well as others; the sowing should be done at the commencement of the wet season, and with the heavy rains likely to fall, then there is danger of silting, and the seed getting too deeply buried. Covering with baskets draws up the plant so rapidly, that it has been found nine inches high, in less than a month from sowing, but with a stem as slender as a darning needle, and quite unequal to resisting the wind, when the covering had to be removed, to allow of vertical extension. Wind is the first and most persistent enemy to the young plant and, to guard it against that during the first year, is the first study of the planter. Many plans have been tried, but the latest and the most successful is cut bataliya into two feet lengths, and in a circle one foot wide, round the spot where the seed is to be sown, drive seven of these six inches into the ground, then with split bataliya work basketwise into them up to the top. This protection will prevent silting and excludes an injurious amount of both wind and sunshine, while it admits enough of both for the health and vigorous growth of the plant. In the mean time, the land may be planted with some crop, that while temporarily occupying the large vacant space and affording shade or shelter, will have a value of its own, and that will help to pay the expense of the operations. Plants that may be used for this purpose are castor-oil, cassava, pigeon pea, cotton teosinte, Indian corn and others, that may suit special soils and climates.

One whose experience is not sufficiently extended to render him an authority should write modestly about permanent shade (which is implied by advising that forest trees should be left for this purpose), but there are principles which require no special experience to understand and vindicate. Shade must have one or two objects in view, when deliberately provided for a cultivated plant; it must either be unable to thrive under the measure of sunshine furnished to the climate in which it is cultivated; or it must, when at maturity, throw too little shade, on its own account, to protect the soil it occupies from the too rapid evaporation of moisture. There may be arborescent plants, that thrive better under shade than fully exposed to the sun, but the writer hereof has not in fifty years found any such plant cultivated either in its own habitat, or in a similar climate. It may be freely conceded, that few if any culti vated arborescent plants can surviv e through several months of tropical drought without either shade or artificial watering during the first, and, in some cases, even the second year of their life; but this is merely because the roots have not reached a greater depth, than that reached by the drought: not that the sun kills them, but the lack of moisture; they would not only stand all the sunshine, but thrive the better of it, if moisture within the field of their roots did not fail them. When the roots have penetrated deeper and spread wider, they will survive a proportionately increased period of drought, without a leaf losing its gloss from sun heat. If a cultivated arborescent plant, that has reached the fruit-bearing age can only survive by a screen being maintained between it and the sun, it is a sure sign that an attempt is being made to cultivate it in an unsuitable climate.

It is claimed for the system of allowing weeds and brush to grow freely under the shade of cacao, that it keeps the soil cool and moist. The theory is urged by the Sinhalese, in defence of a dirty cocoanut estate, but when the undergrowth is reduced to pasture grass, a decided improvement takes place in the cocoanut crop, and a still further improvement follows the ploughing or digging into the soil of the pasture grass. It is probable that the theory in both cases has been invented to justify the slovenly practice. There are cases in which a cultivated plant may benefit by overhead shade, but in no case can the trash that grows under its own shade do it anything but harm. Everything that grows on cultivated land, besides the cultivated plant, robs the latter of some part of its food, and instead of keeping the soil cool and moist, it continues to abstract moisture as long as it lives. In truth, the only way it can serve the cultivated plant, is in digging and being buried. The Ceylon planters already know that weeds are injurious to coffee, and that to keep a plantation clean from the first is much cheaper than a rough weeding three or four times a year. They may be pretty certain that what is true of coffee will not be false of cacao, though not the same type of tree.

We in Ceylon have been taught to believe that soil is rich or poor, according to the proportions of phosphates, nitrates, potash, lime, and soda, it contains, and that the plant cultivated on it will exhaust it, just in proportion to the amount of those elements removed in its crops. That a plant will make its own soil is to us a new experience, whether or not it covers a new idea, it is hard to say. If taken literally it contradicts the whole system of agricultural chemistry, but if the meaning be, that this particular plant thrives tolerably on soil of indifferent quality, it might be more clearly expressed. There can be no doubt that cocoa will take out of the soil certain elements that will ultimately impoverish it, if not replaced, like every other plant; yet it may grow on soil that will refuse to grow some other plant, in the elements of which it is poor. We should get analyses, to let us know what the plant requires, for it is likely that if we know what to use, we shall manure oftener than once in six years, and with something other than its own husks.

The system of opening estates by contract, has never been practised amongst European planters in Ceylon, but it is worthy of consideration, by those who propose to plant cocoa, or Liberian coffee, in the low-country. It would probably succeed in the hands of a European contractor, but no native would work to specifications that debarred him from a crop of kurakkan.—*Ceylon Observer*.

CINCHONA.

CINCHONA CULTIVATION.

A VERY important paper by Mr. David Howard (nephew of Mr. J. Elliot Howard) is referred to as follows in the *Journal of the Chemical Society* for March. It will be observed that he arrives at most important conclusions, among the rest, that mossing does not improve the quality of the bark, and that unlike officinalis, the succirubra bark deteriorates in quality after the tree has passed a certain age. What that age is, has yet to be decided, and it may probably vary in different districts and climates.

NOTES ON CINCHONA BARK.—By D. Howard (*Pharm. J. Trans.* [3], 10, 181).—The author has been enabled to compare the proportion of quinine and other alkaloids contained in the "natural" bark and in that formed by "renewing," *i.e.*, growing after the artificial removal of the bark. This renewed bark is termed "mossed bark," because the tree, after being stripped of its bark, is usually protected by a covering of moss, while fresh bark is being formed. The natural bark was found to be generally inferior to the mossed bark since it had been collected either from the upper stem, or from inferior old trees, whereas the mossed bark represents the product of the main stems of the oldest trees.

As far as the effect of age was concerned, it was found that both the quinine and total crystallisable alkaloid steadily increased in quantity with the age of the trees; this is probably due to the greater maturity of the trees. The trees from which the bark was taken were specimens of *Cinchona officinalis*. The author, on the other hand, confirms from recent experience an opinion previously expressed, that the bark of *succirubra* deteriorates in quality when the tree has passed a certain age. Root bark shows a marked tendency to develop the dextrogyrate alkaloids. A sample of renewed bark, which had been formed without "mossing" or any kind of protection, was also examined, and was found equal in quality to the best mossed bark; hence it appears that the only advantage of mossing is to enable the tree to form bark again with a minimum injury to its health; the process does not appear to improve the quality of bark formed. The author also compares the proportions of alkaloids contained in outer and inner bark; the outer bark not only contain a larger quantity of alkaloids, but these contain a larger proportion of quinine; hence it has been suggested to shave off only the outer layers, without cutting quite through the bark.

CINCHONA CULTIVATION IN CEYLON.

YESTERDAY'S rain was certainly somewhat more than seemed desirable, but examination of berries set and of blossom in spike on the ends of branches does not disclose any harm done. For the tea bushes and for cinchonas especially the pricking out of seedlings*, the weather has been and is all that could be wished. It is curious how opinions differ about the best mode of planting cinchonas. When a Neilgherry planter, lately returned from a visit to Java, was informed that dibbling by means of an alavanga was now the favourite mode, he said "I believe you will find the plan a mistake, and that the proper mode includes large holes and terracing. On the Neilgherries we terrace and in Java Government make it a condition in sales of land that terracing shall be resorted to." It was objected that terraces on our Ceylon soil were so apt to be washed away, the very carefulness with which we weeded being against us. We had personally seen terracing on the Darjeeling tea estates, and we had noticed that the lower edges of the terraces were bound with living grass,* "So it

* What we call *iluk* in Ceylon, and what in India they, curiously, term "jungle."

is with us" was the reply, "and so it is in Java I do not wish to condemn a system which has answered so well in Ceylon, that of clean weeding. But while we do not adopt hand weeding or removing weeds, we resort to *high cultivation* by digging the soil thoroughly three or four times a year, burying the weeds in the terraces or arranging them on three outer edges." We expressed the fear that our Ceylon soil were not generally equal to the support of both plants and weeds, besides which our prevalent weed was not so much any species of grass, as the dreadfu ageratum with its indefinite power of flowering and seeding, drawing from the soil the same principles as required by coffee, while it was useless as a binding material for terraces.

Our *one* difficulty in Ceylon is the *comparative* poverty of our soil or its stiffness. In regard to climate, labour supply, means of communication, &c., we have the superiority. Our visitor fresh from the Ledgeriana plantations of Java confirmed us in the belief that some hundreds of plants growing along the path to Nuwara Eliya and in a patch at the top of the estate were of the very best types, including what had given us anxiety: the forms with rich purple on the backs of the leaves. We had feared an admixture of micrantha. Our visitor quite re-assured us, and Dr. King's report confirms what he said. By our visitor's advice we certainly shall dig, terrace, and manure round those plants, taking cuttings and grafts from them (the latter to be grown on succirubra stocks) and resort to glass for propagation. To the latter suggestion we offered the objection, founded on our reading, that "where cinchonas could not be cultivated without glass they had better not be cultivated at all." Mr. Liddell (for I think I am at liberty to use this very intelligent and practical gentleman's name) smiled and said, "My superintendent objected to glass until I settled the point by providing it. Now he is an entire convert to the practice, finding not only that a larger proportion of plants grow, but that they grow so much more luxuriantly that at least six months of time are saved."

As the local charge for a glass frame is Re. 1·62 per square foot, so that with carriage the cost will be Rs. 40 for 6×4 feet, it is obvious that the expense is only justifiable where a rare and precious kind has to be propagated. As for our two leading species, *C. succirubra and C. officinalis*, I suspect we have been going to too much expense even in ordinary shading, and now that seed is becoming so plentiful, I do not see why broadcast sowing in the open may not be resorted to. If the weakly plants perish from exposure, and if those which survive grow more slowly, so much the better perhaps. The proportion of root to top will be great, and the plants will be hardy, bearing transplantation well. I do not forget that many planters are now just sowing cinchona seed in spots or rows amongst coffee, so that some plants can be left to grow as they stand, while others are "pricked out." Cinchona nurseries, or self-sown seedlings, by the "million" are now common, but the losses in planting out act as a corrective. All this granted, however, and the tendency to "die out" at all stages taken into account, it seems clear that within from six to ten years from the present time Ceylon will be sending enormous quantities of "bark" into the markets of the world. It is on the cards that local manufacture of the alkaloids may be resorted to, on behalf of Government or otherwise. Readers of Dr. King's report will have seen that one of the principal plantations of Ledgerianas is situated 5,300 feet above sea-level. Our own plants at two years old are doing well at from 5,800 to 5,900 feet. But there seems little doubt that, although 5,000 feet indicate the zone of calisayas in their native habitat, they are yet likely to flourish better in the eastern world at altitudes considerably lower. Our own experience with calisayas grown from Neilgherry seed is that many of them get shaky and die off between their third and fourth year, at 5,000 feet and over, but this, as in the case of *C. officinalis*, may be mainly owing to stiff cold subsoil? To give fair play to cinchonas, it seems certain, our soil must be naturally free, or it must be made so artificially. The expense is the difficulty, and any man with experience of the cost of the most ordinary trenching would never be guilty of the insanity or worse of proposing to planters that they should and could afford to move away from their land every stick and every stone and convert the whole surface into walled "rain gauges." Instead of Rs. 20 per acre, or the revised estimate of Rs. 1,000 per acre, Rs. 5,000 would not suffice, or even Rs. 10,000, or any conceivable sum. Ceylon planters never had and certainly have not now rupees to throw away on impracticabilities.—*Ceylon Observer.*

THE YIELD OF CINCHONA BARK.

THE utmost diversity prevails in the experience gained by cinchona planters in Ceylon of the yield of bark per tree in respect of both the crown and yellow description. That different districts and varying altitudes should give different results was to be expected, but even in the same district and under somewhat similar circumstances we have been surprised to learn how great has been the discrepancy between the returns got from trees of nearly the same age. It is evident that the proper age for stripping bark will vary considerably at different altitudes, and nothing but the collection and comparison of the available experience throughout the country, can enable fair and reliable deductions to be made for the guidance of both planters and merchants. There is no doubt that valuable property is lost if not destroyed through premature coppicing and stripping, and yet, on the other hand, we have reason to believe that in some instances trees are left too long to secure to the fullest advantage from their crop of bark. A planter at a high elevation the other day informed us that he meant to cut down a large number of officinalis trees, five years old, to satisfy financial demands in this year of depression, but on experimenting with a few trees he found that instead of three-fourths of a pound of dry bark per tree as he had hoped for, the return was not likely to average much more than one-fourth pound per tree. Now in such a case it is very probable, considering the altitude, that the growth of two more years would double, if not treble, the average crop of bark. Lower down the case is very different, "What do you think,"—writes a Kelebokka correspondent to-day—"of 7¾lb dry crown bark from a 5½ year old tree (large-leaved variety)?" We can only say that we suppose this return is the maximum yet experienced in Ceylon of crown bark for the age mentioned. Our correspondent should have said whether root bark was included. We suppose not. The largest return of red bark reported to us was that obtained by Mr. Chippindall from an old tree in the Nilambe district which made up—with roots, stem, and branch bark—the grand total of 60lb. when dry, but we have since heard of three trees on Durrawella estate, Dikoya, yielding an avarage of 62lb. each, and of another tree on New Forest cut for the third time, the total of three crops including root bark being over 60lb.! In Dalosbagie, Mr. Blackett not long ago cut down a 13-year old tree from which he got, we believe, 28lb. dry bark. It is only by bringing together such varied experience that reliable data can be framed as to the prospects and value of cinchona cultivation in different districts. The large number in our planting and mercantile community who are interested in this important industry, will therefore be glad to learn that in connection with the preparation of a "Ceylon Cinchona Planters Manual" (which has been placed in competent hands) we have arranged to have all the valuable information in the *Observer* files and directories collated and a circular issued to obtain the results of experience gained in different districts in regard to a number of doubtful and interesting points.—*Ceylon Observer.*

CINCHONA IN TINNEVELLY.

FROM Colonel R. H. Beddome, Conservator of Forests, to J. H. Garstin, Esq., C.S.I., Acting Secretary to Government, Revenue Department, dated Ootacamund, 22nd September 1879 No. 859.

* * * * *

13. I carefully inspected all the cinchona on the Tinnevelly hill in accordance with G. O. No. 1140 of 23rd May last. There are only two small plots, one in the Government forests above Papanasam, the other at Chinna Kularati on hills six or seven miles to the south of Courtallam.

14. *The Papanasam Plot.*—This is a small piece of ground of about half an acre cleared in the midst of heavy forest at the eastern side of the Payar Shola; the exposure is north-east and the situation very moist; the elevation about 3,400 feet above the sea. The plants were sent from the Neilgherries and put down by Mr. Athol MacGregor in 1866 the site was then fenced in and probably left to Nature; though I believe that a hillman was supposed to look after it in its infancy, it was under the Revenue authorities, and was never, I believe, transferred to this department; the fences have long since been destroyed by wild elephants, and there were recent traces of these animals all about the locality. There are now standing twenty-nine large trees of C. *Succirubra*, all much the same size, the bolls tall and healthy, but few or no lateral boughs, and those mostly broken, and very poor heads; in fact, altogether deficient in leaf, having much the appearance of having suffered from a violent hurricane, but it is possible that they may have been injured by black monkeys, which were very abundant about the vicinity. I measured three of the larger trees with the following result :—

		Ft.	In.
No. 1.	Height	50	0
	Girth at base	2	6½
	Girth breast high	2	8
	Girth at half length	1	6½
No. 2.	Height	49	9
	Girth at base	2	8
	Girth breast high	2	0
No. 3.	A double stem from close to the base ...	...	...
	Height of larger stem	52	7
	Girth near the base	2	8
	Girth breast high	1	11
	Girth at half length	1	8½
	Height of smaller stem	42	0
	Girth breast high	0	10½

Besides the twenty-nine planted trees there are numerous self-sown saplings 18 to 20 feet high; these are very close together, without room to develop properly.

In addition to the *C. Succirubra* there are a few trees of *C. Officinalis*, but these are all of very poor growth.

15. *The Chinna Kularati Plot.*—The elevation of this site is 2,800 feet above the sea; there are only eighteen C. *Succirubra* trees standing 5 to 6 feet apart on two terraces at the edge of a native coffee estate close to dense forests; they are all about the same height, 30 to 40 feet, except one, which is stunted and of poor growth from being densely overtopped by a forest tree; they have straight clean bolls with no lateral boughs and fine healthy heads; they are, however, all too much in the shade of the forest; the largest tree was 37 feet 2 inches high, 2 feet in girth at the base and 1 foot 5 inches breast high They are evidently looked after by the owner of the coffee estate. The climate here is nearly as moist as on the Papanassam hills; the trees were said to be ten years of age, and certainly looked much younger than those in the Papanassam block, but by G. O. No. 2362 of the 8th October 1867, they appear to have been planted at the same time.

Acting Secretary.

SERICULTURE.

SILK IN DEHRA DOON.

THE Superintendent of Dehra Doon reports most favourably upon the silk-worm breeding experiments, which he carried out last year, on behalf of Government at Dehra. The chief merit which commended itself to the local Government, and induced it to attempt sericulture in that part of India, is the facility, which is afforded by the proximity of the elevated station of Mussoorie to which silk-worm eggs can be sent in the cold weather in order that they may not be hatched until the mulberry trees produce their new leaves. Besides, the conservation of the eggs in the hills prevents a weakly breed of worms, which is the result of hatching in the warmer climate of the plains. The eggs, for the first experiments, were brought down from Mussoorie in 1879 as soon as the new shoots appeared on the mulberry trees. Unfortunately a frost occurred shortly after the eggs were hatched, and this destroyed the young leaves, in consequence of which numbers of the young worms died from starvation. The Superintendent, however, succeeded in rearing a number of caterpillars, from which he obtained some 500 cocoons, 100 of which were sent down to Calcutta to be reported upon. The following extract from the letter of a firm of brokers, at Calcutta, proves, what had already been hoped, that finer cocoons can be produced under this system of preserving silk-worm eggs on the hills, than under the system which has to be followed in Bengal. The extract to which we refer runs thus:—

"Could we get these cocoons in a good state of preservation, we could make silk from them far superior to anything we are at present able to turn out, and if such an article could be forwarded to Europe, in large quantities, Bengal silk would gain a prestige in the markets which it has never yet held." We may mention that the instruction of natives, near Dehra, in silk-worm breeding, has commenced, and that an offer has been received by Government from a German firm to undertake an extensive filature business in connection with the Dehra breeding establishment. There is some prospect, therefore, of this pioneering enterprise which Government have undertaken leading to the establishment of a silk-working industry on the hills.—*Indian Herald.*

SERICULTURE IN CEYLON: WHY NOT UTILISE THE CINCHONA CATERPILLARS?

(To the Editor of the Ceylon Observer.)

SIR,—If I am not mistaken you see regularly that most valuable publication, the *Journal of the Society of Arts*, and it has therefore surprised me somewhat not to have noticed in your paper ere this any allusion to the very important papers which have appeared during the last 12 months on the subject of sericulture. I refer to the following: *Journal S. A.* for 10th January, 9th May, 6th June, 6th February, 13th February 1879, and 15th March 1880. I think it worth while to call your attention to these articles in connection with the war which is being waged at present against the poochies. Very considerable expense is being incurred in searching for and collecting and destroying the caterpillars which infest the cinchonas. The last operation is popularly supposed to add practically nil to the cost of collection, but the question arises as to whether this wanton destruction of what has cost money and time to collect is not a very wasteful and short-sighted policy. Having collected these caterpillars, might I suggest the advisability of rearing them to the chrysalis stage on the fair chance of getting a return from the cocoons? I have been shown some recently, which were collected from the branches of cinchona trees and which, to my unpractised eyes, bore much resemblance to the valuable tusser cocoons described in the articles before referred to, and which are known to exist in Ceylon.

It might, perhaps, be thought a hazardous experiment thus to take so [illegible] an enemy of what promises to be one of the most valuable products of Ceylon under our protection, but I think it can be shown that by this course we are really benefiting the cinchona by placing the breeding of these worms, as it were, under inspection. Let us suppose for instance, that we have our cocoons, and that the moths are about to emerge; it is easy to distinguish the sex by the antennæ, which, in the male are broad, and in the female narrow. I learn, moreover, from Mons. Wailly and others, that the moths of this large race are extremely quiet, allowing themselves to be taken by hand and placed anywhere, pairing readily and for a considerable time, a most improtant thing, and the females laying their eggs for several days without even damaging their wings.

The following is an extract from a letter from Major Coussmaker to M. Wailly, dated 27th July 1879: "My system of rearing is very simple and methodical. I keep all my seed-cocoons in a basket, with the pedicles uppermost. At intervals, between 6 and 11 P. M., I look at them, and if I see any moist at the top, I tie them on to a branch of any tree or shrub in my garden, and at daylight I find that the females are paired in the vicinity of their cocoons, while the males have gone away to seek for mates.

"They are left in that condition all day, and at sunset, or when I am going out for walk, I take the females, let the males fly, and put the females to lay their eggs. The next morning I take the eggs away, and put them in a small box, or something of the kind, safe from rats mice, and ants.

"In nine days they hatch out, and I put them on to shrubs, over which I put screens of split bamboo. As the worms grow, they eat the shrubs quite bare, while I move the screens as necessary. To facilitate this moving, I have planted my shrubs in hedges, and now it is only a matter of the food and number of worms.

"From a month to six weeks, according to the moisture and luxuriance of the foliage, the worms take to make their cocoons, and, as far as I see, success seems certain. The plants I use are the varieties of lagerstrœmia, zizyphus, terminalia, and carissa. I am not aware as to whether any of these trees can be obtainable in England, or whether the worms will hatch out there. The moths paired and laid eggs in 1874, but did not hatch. I hope that you will be more successful."

Major Coussmaker resides, I believe, at Poona, and has been very successful in his efforts to develope sericulture in India, more especially that of the tusser moth; and under such regulations as his, I think, there would be no danger in multiplying the breed. But the next thing to consider is their food. I understand that they readily feed on the leaves of lagerstrœmia, a shrub well-known in Ceylon, also on the castor oil plant. Then there are the cinchonas themselves; at the rate we are planting them, I imagine that the mere prunings would go a considerable way; and there is practically no limit to the production, especially if we bear in mind that the secretion of alkaloids is known to be stimulated by all such expedients as tend to check a too great luxuriance.

As an indication of the importance financially of the subject, I may mention that whereas a short time ago mulberry silk was almost double the price of tusser in the London market, owing to the difficulties in working it up and dyeing; since the difficulties have been successfully overcome by such persevering workers as Mr. Thomas Wardle and Messrs. Clayton & Co., the relative position in the price has been reversed. It is of course better, if possible, to reel the silk before the moth emerges, but machinery has now been constructed by which the silk from broken cocoons can be utilized; if desired, however, the contents may be destroyed without damage to the silk by boiling. The fine silk from a single tusser cocoon has been found to measure over three-quarters of a mile in length.—Yours faithfully,

FOR CEYLON COMPANY, LIMITED,
C. W. HORSFALL, MANAGER.

April 3, 1880.

TOBACCO.

INDIAN TOBACCO.

ANY scheme which promises to increase the revenues of India without pressing too hardly on the means of the population, is naturally always welcome, and a communication which has reached us from an English correspondent, describing with a good deal of force a plan for this most desirable result, commends itself to our attention at once.

The writer, observing that the people of India undoubtedly prefer indirect to a direct taxation, and instancing the tax on salt, necessary, and on opium, drugs, and spirituous liquors which are luxuries, as the great sources of revenue on this system, proceeds to suggest that by encouraging the cultivation of tobacco all over the country, and imposing a tax upon its growth at the same time, a very handsome addition to the national income may be secured without forcing even a semblance of hardship on the people. Tobacco, he says, which is almost universally taxed in other parts of the world, is not taxed at all in India, though nearly every man, woman, and child above ten years old smokes it in some form or another.

The scheme he suggests is analogous to that in practice with regard to opium growing. He notices that an abortive attempt to tax manufactured tobacco was once made, but the plan was speedily abandoned. He recommends that all tobacco cultivation should be sanctioned only under license. The plant should be grown in plots of ground of not less than an eighth of an acre in extent, so as to be easily discernible on the ground, the crops when grown to be purchased by the Government at a fairly remunerative rate to the cultivator; the leaf when gathered in to be stored in central depôts and prepared for use under due supervision and management. Afterwards it would be saleable the writer observes, on account of Government to wholesale dealers at a very handsome profit to the State. He would advocate the distributing of good foreign seed among the cultivators and the giving of rewards for the best crops; the cultivation and production

would thus be stimulated and improved, superior manufacture would be insured; and we are certainly inclined to agree with him when he declares that there is reason to suppose that India could produce tobacco quite as good as that of Manilla or Havanna to an extent which would allow of exportation in great quantities. Taking the present average price of native grown tobacco in the Indian bazaars at three pence per pound, he estimates that after acquiring a monopoly of its sale, the Government could make a profit of four millions and-a-half pounds sterling per annum, by raising the price to sixpence per pound. Here, however, he is clearly at fault in making no deduction of all the expenses of depôts, manufactories, and establishments, and his figures are obviously fanciful when he assumes that there are twenty millions of families in India, each consisting of ten persons, who consume between them two pounds of tobacco monthly.

It is true that he suggests the utilizing of all the Government jails, as central depôts, and the employing the prisoners, especially the females, in preparing the leaf for the market. But the creation and maintenance of great industries are not usually to be accomplished without great expense. To start one is often a very costly and doubtful experiment. The present consumption of tobacco is no doubt large, but we have no means of ensuring that it would remain so if the price of the article were doubled. The consumers are exceedingly poor to begin with. The cost of the production of the leaf at present is infinitesimally small. The cultivator has usually a small plot of ground probably close to his hut. He grows in this a few herbs and vegetables for his own consumption, and in one corner of this little plot he has a few tobacco plants which supply his needs. But if this sort of cultivation were forbidden, the measure would undoubtedly appear extraordinarily harsh and oppressive, and might, if not evaded, suppress the taste for tobacco altogether. The ordinary ryot, accustomed to get his supply for nothing, would not, and could not, go into the market to purchase the luxury at a high price.

On the other hand it is probable that tobacco cultivation on a great scale and accompanied by improved methods of preparation of the product would under active supervision and in the hands of private enterprise, develope into a highly lucrative business, from which the Customs Department might look eventually to considerable profit. In any case, some statistical informations might be easily obtained as to the consumption of tobacco generally by the population, as to the different qualities of it now grown, and the prices they have in the market, the probable cost of improved manufacture and preparation, and a variety of other points connected with the subject which would materially aid in the formation of a just conclusion on the merits of our correspondent's suggestion.

The development of a very extensive trade, both export and domestic, in tobacco, which is certainly not beyond the bounds of probability, is a sufficient inducement for inquiry at all events.—*C. & M. Gazette.*

TOBACCO CULTIVATION.

IN a recent issue we indicated tobacco cultivation as a new career for educated natives, in which they might earn an honest and decent livelihood without any considerable capital outlay. We now proceed to give some practical hints on the culture of this plant taken from the annual report of the Madras Agricultural Department for the year ending 31st March 1878. The writer of the report points out that tobacco was brought into India, most probably by the Portuguese in the commencement of the seventeenth century. He thus describes the value of the plant:— "Although tobacco has lost its fame as an universal remedial agent in sickness, it still holds a high reputation among medicinal plants. It chief use, however, is as an article of luxury. The consumption of tobacco increases every year. To satisfy this demand, the production of this plant assumes annually larger dimensions; it has become a staple product of several countries; whole nations find in the cultivation, manufacture, and trade of this article, the means of their support, the source of their affluence and wealth. In many countries the revenue is chiefly derived from tobacco; prohibitive laws have made room for decrees encouraging and facilitating the production and manufacture of this commodity: agents are appointed to instruct the cultivator how to raise the best plants, and how to produce the heaviest crops; schools have been founded to initiate the rising question into the art of treating the leaf after its production. Everywhere it is recognised that, in the development of tobacco cultivation, there lies a source of wealth expanding in proportion as intelligence guides the undertaking."

Experience has shown that a warm moist climate is favourable to the production of good tobacco; and that of the many conditions affecting the quality of the product the most important is the climate. The superior quality of Cuban and Manila tobacco is mainly due to their particular climate. But we are told that tobacco cultivation is often very remuneratively carried on in countries possessing an unfavourable climate. In such cases the deficient climatic conditions are "partly compensated for by making the other conditions which can be controlled by the cultivator, the most favourable for the production of this commodity." Next to climate the soil affects to a great extent the quality of tobacco. The writer of the valuable reports before us says: "The tobacco plant thrives best in a soil rich in vegetable mould. The vegetable mould is however not so much required to supply the necessary plant food as to keeping the soil in a good physical condition. It may be said that no other plant requires the soil in such a friable state as tobacco. A light soil, sand or sandy loam, containing an average amount of organic matter and well drained, is considered best adapted for raising smoking tobacco; such a soil produces the finest leaves. The more organic matter a soil contains the heavier is the outturn; the leaves however become thicker and the aroma less. As in tropical climates the physical properties of the soil play a prominent part in its productive capabilities generally, and the presence of organic matter in the soil tends to improve these properties, it will rarely occur that in such places a soil will be found that contains too much humus. The more clay a soil contains the less it is adapted to the production of fine smoking tobacco, on account of its physical properties being less favourable to the development of the aromatic principles in the leaf which becomes also generally thick and coarse, but the outturn on such soils is generally heavier than on a mere sandy one. A clay soil however possessing a great amount of humus may, if properly tilled, produce an ordinary smoking tobacco, and may even, if great attention is paid to the selection of the variety, &c., produce leaves for cigar wrappers. By deep ploughing and heavy manuring tobacco may be successfully grown on poor soil. Even the best soil does not in its natural state possess the elements of plant food in such a form as is most conducive to the production of a fine tobacco leaf. Any deficiency of the necessary plant food must be supplied in the shape of suitable manure. Fold yard manure may suffice when tobacco is cultivated in proper rotation, but the application of special manure like *carbonet of potash, sulphate of potash* &c., will greatly enchance the value of the outturn. The element most needed by the tobacco plant is *potash*. To supply the *potash* required by the tobacco plant 200lb. of good saltpetre per acre would be sufficient, in most cases a proper rotation of crops is advantageous in the cultivation of tobacco as of many other crops, though it may be grown successfully on the same land in succession under special circumstances. Cereals and pulses are recommended as very well adapted for cultivation in the course of rotation. We learn from the Report of the Madras Agricultural Department before us that "by digging over his rich alluvial soil 2 feet deep, and manuring at the rate of 25 tons per acre and paying the utmost attention to his tobacco the Dutchman is is able to compete successfully with France and Hungary, and receives as much as Rs. 44 per 100lb and a gross income of Rs. 700 per acre planted with tobacoo." The soil intended for a tobacco nursery should be broken up to the depth of 1½ foot some months before the sowing season, and a drain should be dug round the nursery, the earth thus obtained being utilized in raising the surface. The soil of a tobacco nursery cannot contain too much organic matter. About 7,260 plants are required for an acre, and to raise this number of plants an area of 50 square feet would be required. But as the plants are apt to be injured during their first growth and in process of transplantation, the cultivator is advised to raise double the number of plants actually needed. Nearly 7 acres could be planted with the seedling raised from one ounce of tobacco seed which contains about 100,000 grains; as, however, even the best tobacco seed has not a very high percentage of vitality, between half an ounce and an ounce of seed is generally sown to produce the number of plants required for one acre. The plants will appear about a week after sowing, and during the first stage of their growth they require very careful treatment; any weeds appearing must be removed and insects injurious to the plants must be killed. In about seven or eight weeks after sowing, the plants will be fit for transplanting. The land intended to be planted with tobacco should receive several deep ploughings not less than 9 inches deep. We read: "No other crop will better repay the expense of proper preparation of the soil than tobacco. The fineness of the leaf, and the aroma of the tobacco depend to a great degree on the preparation of the soil. The land should be ridged immediately before planting. The distance apart at which to place the ridges depends on the quality of the soil and the species of plant to be raised. One species has large leaves, another has short ones, the leaves of some varieties stands at an acute angle and of others more nearly at right angles to the stem, thus occupying more or less space. With good soil the ridges must be made further apart than in a poor one, because a good soil produces larger leaves." The planting tobacco should take place only in the evening or at night. But if the weather be cloudy, the operation might be performed during the whole day. The planting is nearly the same as with cabbages, but requires more care, the plants being more tender. The plants must be watered immediately after they are planted and they should also be shaded during the first few days. When the weather is dry, water should be applied twice a day, *viz.*, morning and evening. When the plants are 6 to 9 inches high they should be hoed. Some weeks afterwards another hoeing is necessary. Frequent hoeings are needed to keep the soil loose, friable, and free from weeds. Insects which attack the tobacco must be killed at once. The plants will commence to flower about two months after planting, when from 2 to 7 feet high. When the flower buds appear, they must be broken off, and with them the top and also the bottom leaves. The plants commence to ripen about three months after being planted, this is indicated by the leaves assuming a marbled appearance and a yellowish green colour. The leaf being matured, it should be harvested only after the dew is off the plants and not on a rainy day. There are two modes of harvesting—gathering the leaves singly and cutting down the whole plant. For India the latter mode is better adapted than gathering the leaves singly. For cutting down the plants a long knife or chopper should be used. During bright weather the plants should

not be allowed to lie exposed to the sun on the ground or they will become sun-burnt and lose in value. The plants should be left one day in the field; and if a very dry wind should be blowing some mats or other covering should be laid against plant most exposed to it. The next day the leaves should be removed to the drying-shed in a cart supplied with a frame-work so that the plants may be hung. While, in the drying-shed the leaves must be examined carefully every day, some plants dry quickly, others more slowly, some tobacco is fit for smoking a few weeks after drying, whereas others burn very badly at that time, but nevertheless sometimes becomes a good burning article after being stored for several months. To improve smoking tobacco, a flavour is sometimes given to it artificially by the manufacturer. It should not be forgotten that the value of a cigar depends, not only on the intrinsic value of the leaf, but to a great extent on the mode of manufacturing the article. An inferior tobacco which often would not find a market, is sometimes so much improved by artificial means that it can compete successfully with the genuine fine article. The manufacture of tobacco is, therefore, quite as important as its cultivation. This should always be very carefully borne in mind.—*Hindoo Patriot.*

SEVEN PRIZE MEDALS awarded to GOODALL'S HOUSEHOLD SPECIALITIES. A single trial solicited from those who have not yet tried these preparations.

Goodall's Yorkshire Relish

THE most delicious sauce in the world; enriches hot joints, stews, chops, fish, &c.; with soup it is charming, blends admirably with all gravies; makes cold meat a luxury; makes the plainest viands palatable; the daintiest dishes more delicious; a great addition to cheese; every dish is improved by its addition; epicures pronounce it the best sauce; beware of colourable imitations.

CAUTION.—It having come to our knowledge that an imitation of our celebrated Sauce, the Yorkshire Relish, is being palmed upon purchasers, we beg that they will insist upon having the only genuine Yorkshire Relish, bearing a label with the Trade Mark, a "Willow Pattern Plate," and our name, "GOODALL, BACKHOUSE and Co., LEEDS," with a protecting label over the stopper. We are sorry that respectable tradesmen should lend themselves to such an imposture for the sake of a little extra profit. Sold by Grocers, Oilmen, Chemists, &c., in bottles, 6d., 1s., and 2s. each.

Goodall's Baking Powder

AWARDED Seven Prize Medals for superior quality. The best in the world. Defies comparison. Makes delicious puddings without eggs, pastry without butter, and beautiful light bread without yeast. One trial will convince the most sceptical of its superiority over others.

Sold by Grocers, Oilmen and Chemists, &c., in 1d. packets, 6d., 1s., 2s., and 5s. tins.

Goodall's Custard Powder

FOR making delicious custards without eggs, in less time and at half the price. Delicious to plum pudding and jam tarts; delicious to stewed rice and all kinds of fruit; delicious to everything; delicious alone.

Give it a trial.—Sold in boxes, 6d. and 1s. each, by Grocers, Chemists, Italian Warehousemen, &c.

Goodall's Egg Powder

ACKNOWLEDGED to be the only real substitute for eggs yet discovered; its action on Cakes, Puddings, &c., &c., resembles that of the egg in every particular, enriching them in colour and flavour, rendering them most wholesome and nutritious. One penny packet will go as far as four eggs! and one sixpenny tin as far as twenty-eight!

Sold everywhere, in 1d. Packets, 6d. and 1s. Tins.

Goodall's Ginger Beer Powder

MAKES three gallons of the best Ginger Beer in the world for threepence. Invaluable for producing a delicious and invigorating beverage, possessing valuable medicinal properties, thereby rendering it the most wholesome and perfect beverage ever discovered for both winter and summer use, is easily made, and acknowledged the best and cheapest.

Sold in packets, 3d. and 6d. each, by all Grocers, Chemists, and Italian Warehousemen, &c.

Goodall's Quinine Wine

IS invaluable for indigestion nervousness, gout, rheumatics, &c. A wineglassful twice or thrice a day will be found both grateful and efficacious in all cases in which a cordial tonic is required, far superior to sherry and bitters or bitter beer.

Sold by Chemists, Grocers, &c., at 2s. per bottle.

Goodall's Mushroom Ketchup

CONFIDENTLY recommended to all true lovers of the Pure Mushroom. Prepared by a special Steam process, from the PURE JUICE, producing a FULL AND RICH FLAVOURED KETCHUP, unrivalled for its GREAT STRENGTH! PERFECT PURITY!! and UNSURPASSED FLAVOUR!!!

Sold in bottles at 6d., 1s., and 2s. each, by Grocers, Oilmen, and Italian Warehousemen all over the kingdom.

Goodall's Brunswick Black

FOR Painting Stoves, Grates, Iron, Tin, &c. This invaluable composition is superior to any yet offered to the public, possessing great brilliancy and thoroughly protecting the articles it is applied to.

Sold in bottles at 6d. and 1s. each by Grocers, Oilmen, Chemists, Italian Warehousemen, Ship Store Dealers, &c. Shippers and the Trade supplied by the Sole Proprietors,
GOODALL, BACKHOUSE, & CO., White Horse Street, Leeds, ENGLAND.

WINES, &c.

INTRODUCED BY

W. & A. GILBEY'S

SPARKLING "BRUT SAUMUR" CHAMPAGNE

FROM

FRANCE.

FIRST SHIPMENT TO THIS COUNTRY.

Castle "Brut Saumur."

Is the produce of selected grapes grown in the extensive wine districts of Saumur, an invaluable sparkling wine to those who require wines free from all saccharine. It is strictly what is known as a "Brut" or "Natural" wine, that is to say, no saccharine has been added since the completion of the fermentation.

	Rs.
Quarts per dozen	28
Pints " "	30

Dr. Druitt writing in the *Medical Times and Gazette* of the 29th March 1879, states as follows :—

"Added to the practical experience of the last dozen years "during which I have known these wines, I may give "the following theoretical reasons for the superiority of "'*Vin Brut*,' as a stimulant in many cases, more particu- "larly dyspeptic, and others where the consumption of "sugar should be avoided.

"*First.*—The Brut wine is STOUTER and MORE GENEROUS.

"*Second.*—It is more APPETITE-COMPELLING.

"*Thirdly.*—The extra degorgement and the absence of dosage "with Sugar and Brandy render "Brut Saumur" less liable "to disagree while it meets for INVALIDS A WANT THAT HAS LONG "BEEN FELT by the Medical profession, but which perhaps "previously has not been within general grasp (*viz.*) that of "a PURE, SPARKLING, and MODERATELY STIMULATING BEVERAGE "at a reasonable price. The man in perfect health may "drink which he likes best, without fear of the small "quantity of sugar in the ordinary wine, but if he prefers "a dryer wine here it is."

The following also is the report of Dr. D. Waldie, F.C.S., after analysis :—

"The results of this (analysis) indicate that the Brut Saumur "is a natural wine, like other NATURAL UNSACCHARATED or "UNFORTIFIED wines, the matter and properties of the consti- "tuents of which have been ascertained, so far as I can "judge, from the analysis, it is a *good, wholesome wine*, "possessing the properties belonging to the BEST NATURAL "WINES, without the peculiarities of certain kinds objection- "able in many cases such as the astringency of Clarets in "the excessive amount of alcohol or sugar in others."

With the opinions of two such well-known authorities both in England and in India, we offer the above wine to our constituents and the public, our stock however is small, the shipment being only a trial one, early application therefore is necessary to prevent disappointment.

THE

CALCUTTA MUSICAL ESTABLISHMENT,

No. 13/1, Government-place, East.

(LATE BURKINYOUNG & CO.)

FOUNDED, A.D. 1814.

PROPRIETOR—CHARLES GOULD.

THE SMITH AMERICAN ORGAN,

Wholly new designs and effective combinations in Reed Organs.

THE American Organ has been, and still is, the most popular and valued instrument for Churches and Chapels. Immense numbers of them are used in public worship, and it has been found that no other Reed Organs have so much sustaining power joined with such melodious quality of tone.

Style No. 10, *Seven Stops.*

This Style is furnished with two complete sets of reeds of five Octaves. Each set is divided and has a separate stop, for the upper and lower half. The upper half of the first set of reeds is named Flute, and the lower half Principal. In the second set the upper half is named Dulciana, and the lower Diapason. The first set is an Octave higher in pitch than the second, so that the instrument has practically a compass of six Octaves. By having the sets divided, it will be seen that more effect can be produced. The remaining stops are Tremelo, Diapason Forte, and Principal Forte. [*Net Cash, Rs.* 400.

Style No. 16, *Ten Stops.*

This instrument has two-and-a-half sets of reeds, and an Octave of Sub-bass. It has ten stops, *viz.*, Diapason, Dulciana, Flute, Principal Kulophon, Sub-bass, Tremelo, Principal Forte, Diapason Forte, and Octave Coupler. The last stop doubles the power of the Organ, and with the aid of the Sub-bass renders it a powerful and effective instrument for Churches and Halls; at the same time its power is not obtained at any sacrifice of delicacy, and it will be found a most desirable instrument for home use. [*Net Cash, Rs.* 650.

Style No. 20, *Nine Stops.*

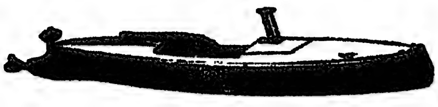
This instrument has three complete sets of reeds. Two of the sets are like those in the preceding Styles, having the Principal and Forte Diapason and Dulciana stops. The third set is new and distinct in quality, the upper half is named "Aulodia" and the lower half "Fagotte." The tones of this set are unrivalled in clearness, smoothness, and tender beauty, and their effects in connection with the swell are surprising.

This Organ is one that will be approved by all persons of refined taste. [*Net Cash, Rs.* 750.

***N.B.*—The above prices are exclusive of packing charges.**

STEEL STEAM CANOES, STEAM GIGS, STEAM LAUNCHES, all of Steel throughout with patent 3 cylinder "Compound and High Pressure (combined) Expansive Engine," convertible from the latter into the former by the one Lever that solely controls its motion, having no dead-centre and *capable of instantaneous reversal* while running at the highest speed. Portable Folding Boats, Corrugated Iron Sheds with patent Pillars, Portable and Stationery 2 and 3 Cylinder Engine, and Road Locomotives. For full page illustrated advertisement, see February, March, and April numbers.

24 ft. × 4½, draught 1·3—holds 7 persons



Rs. 1,700 and Rs. 2,000, weight 12½ mds.

Light draught Steel Barges or Flats adapted for the carriage of Produce in Inland Waters, Creeks, Shallow Rivers and Canals with very powerful little "Tug Steamers" of light draught, and having four Propellers or Paddles and twin Propellers. Seaworthy Launches, &c &c.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.

CORRESPONDENCE.

THE AWAH ESTATE.

TO THE EDITOR.

SIR,—Will you allow me to note a few remarks with reference to your article on Agriculture in the North-Western Provinces in your May number?

When discussing the improvements that are being carried out on the Awah estate it should be remembered that the estate is not compact or uniform, to be classed as one tract or district; it is scattered over more than four hundred villages lying in five several collectorates, within points one hundred miles apart from east to west, and fifty miles apart from north to south. No such general statement as "Awah is a district where canal water is not to be depended upon" can apply; much of the estate gets canal irrigation, but there are parts devoid alike of canals and wells.

For my own part I see many difficulties in the way of legislation about cattle breeding; and I am inclined to think that in those few parts of the country where breeding cattle for the market is systematically carried on, and where it is the interest of the people to secure good young stock, that alone should prove a sufficient incentive for them to use only superior sires when such are placed at their disposal. What mischief is at present done, is caused principally by allowing the cows to be served by the ordinary working plough cattle, and this occurs mostly where there is no good village sire, or 'Brahmini Bull' as you call him. Where there is a village sire, he is out grazing with the cows all the year round, and they are ordinarily served by him; a working bull is only turned loose at certain seasons of the year, when work is slack, and he can be spared to pick up his living by grazing. To let loose a "bijjar" or Brahmini bull, is simply the native fashion of setting aside a bull for breeding, as distinguished from working purposes; but as the bull becomes thenceforward public property, and the donor derives no pecuniary benefit from him, it is only a well-to-do man who can afford to devote a bull to this purpose, and that only when incited by the pious desire to honour the memory of a deceased parent. Sometimes meanness induces a cheap conformity with the requirements of piety, and an inferior animal is turned loose, but I do not think that this is generally the case, and in localities where the boon will be appreciated, the young 'bijjar' is carefully selected. On the other hand he gets his liberty at, generally, too early an age; this arising from the necessity of setting apart a bull that has never been ringed for labour. When you have him, the 'bijjar' is the best sire that at present is procurable; he is set apart for breeding, does no work, and should by custom get ample grazing, as all alike should let him graze on their lands, even if he trespasses on cultivation. In closely cultivated districts, however, and where crops are worth much more than cattle breeding, he often gets roughly driven off, and voted a nuisance, and in this state of things is often annexed by the Mussulman butcher, or the Branjara cattle dealer, there being no one master or owner to protect him. A system which shall secure that only suitable young bulls be turned loose 'as bijjars,' and which will also protect their well-being when at large, seems to be the simplest method of improving cattle breeding.

But, as you say, cattle of superior quality will require better feeding; and here is the great difficulty even if the ordinary cultivator had (which he has not) the means to purchase superior plough cattle, he is not able to feed them properly; poor men with small holdings cannot afford it; while well-to-do men with large holdings already do as much as they can. This great difficulty of the poverty of the tenant, and the system of such holdings, is constantly cropping up in the face of improvements; there is no economical gain in having an improved plough and better team of oxen, that can do work more expeditiously and effectively than the ordinary grubber with its miserable cattle, unless the tenant's holding is

large enough to give the new team full work; let alone his having means to buy and keep up the stock. I would note, by the by, that you seem unaware that the Cawnpore plough has been fitted with a single handle; it was so fitted when working at the Aligurh district show in March last, and similar ploughs are on trial at Awah.

The case as to the use of the agency of *bunnias* for distributing improved seeds is simply this—The *bunnias* are the seed and grain dealers of the country: they buy up the grain produce from the producers who are their regular customers, store a certain quantity for local wants, and dispose of the surplus for foreign consumption in the best market they can find. When seed time comes, they supply their customers with advances of seed grain from their local stocks, to be repaid at harvest. The business is regularly organised, and is one of great detail; there must be a grain dealer, principal or agent, in every village of any size, who knows all his customers, distinguishes the sound from the unsound, and watches what use is made of the advances. If a landowner is to distribute seed grain himself, he must create an organisation of this kind, take the business out of the hands of the existing local dealers, and in fact become himself the *bunnia* working through a number of agents. Having driven out the existing trade agency, he would himself have always to stand in its place for future. It is extremely doubtful whether he could carry on this business with any profit to himself, and with only increased benefit to his tenants. Hence the advisability of using the existing agency for distribution, the landowner simply going to the expense of supplying the seed merchants with improved seed in place of the inferior stocks they have in hand. Once introduced, the seed will multiply itself, and year by year there will be a larger stock for distribution; and if the seed proves a success, the old inferior seed will be no longer used. Apart from this, it is to be remembered that the *bunnias* are alive to their own interests, and that they will be the first to realise what profit is to be derived from the higher prices the produce from the improved seed will command in the foreign market. If this result is not achieved, the experiment fails. The only danger is, of course, the seed-merchant's tendency to foist off as bad seed as he can on the farmer: which on the other hand the needy farmer tries to get it as cheaply as he can, and will not pay the price that carefully selected seed demands. Apart from this danger, I should hope to improve seed grain by careful selection, cleaning, and winnowing on the part of the seed-merchants, more readily even than by trying to introduce these processes to the producer; while I feel certain that in the matter of preparation of grain for market, the grain-dealer is the first person on whom the advantages of cleaning and winnowing should be impressed.

W. BENSON.

21st May 1880.

BAMBOO PAPER-STOCK.

TO THE EDITOR.

SIR,—In my last letter I enumerated some of the different varieties of bamboo which I considered most suitable for paper-making material, available in the southern districts of India, quoting specially Arrakan, Burmah, and the Tenasserim Provinces, those districts being more peculiarly adapted to the industry I desire to introduce, due to two causes, *viz.*, climatic influence, continuously elevated temperature combined with great moisture inducing prolific growth, and possessing extensive tracts of jungle or native forest already occupied with vast existencies of bamboo growth, affording a practically inexhaustible supply. Such districts, moreover, being mostly within a moderate distance of the coast, and all accessible by navigable streams affording floating facilities, water carriage being notably the cheapest means of transit.

Assuming, then, that pending the formation of regular plantations, the jungle or native forest has to be resorted to for the supply of bamboo, it may be well to note the most practical and readiest means of collecting and storing so very bulky a commodity as bamboo, bearing in mind that my programme involving the employing of young, so-called season shoots only, and these at a very early stage of their growth, it follows that such collection from the native forest must of necessity be limited to a very short period—lasting only some weeks, and this during the rainy season.

At this early stage of growth, cutting down a stem of bamboo is a very simple operation, one blow of a heavy knife (the native *dâh*) being sufficient, and as the young shoots have no lateral branches, so soon as cut and divested of their tops, they can be made up into rafts, launched into the adjacent stream, and floated to a station, where having arrived, the raft can be towed into a pond, and there kept to await its turn for crushing.

In previous communications I have stated that the young shoots should be crushed when fresh and green, or as soon thereafter as possible, inasmuch as containing from 60 to 70 per cent. of moisture, if allowed to dry before crushing, the moisture alone evaporates, leaving deposited in the corpus of the dried stems, the sappy constituents consisting of silica, sizin, and other compounds, which if the shoots are crushed when fresh and green, will to a great extent be expressed with the sap, whereas, if the stems are allowed to dry, not only is the crushing operation more difficult, and the subsequent chemical treatment then required infinitely more costly, but the quality of the ultimate fibre much deteriorated, being harsh and woody.

Although I believe the young stems of the bamboo may be kept submerged in water for a considerable time, without material injury, it is desirable they should (for the reasons stated) be crushed as speedily as possible after cutting, and as in a moist, hot climate, especially at the wet season, when the young shoots would be cut and crushed, fermentation followed by decomposition, in other words rotting would rapidly ensue; it follows that artificial drying must be resorted to, this operation, however, is simple and inexpensive, and the crushed and dried stems would be roughly baled up for storage and conveyance to the Central Stock Factory at convenience.

I must, however, repeat my former observations under this head in your columns; that even this treated, the bamboo being so bulky and light a commodity, cannot support the cost of carriage for long distances, and therefore in this crude condition cannot become an article of export or merchandise. The position indeed is similar to that of a farmer in this country who can only send his hay or his straw to market, governed by the distance of the said market from his farm. Thus the collection of bamboo from the jungle or native forest must be governed by the cost of carriage to the Central Stock Factory.

Such difficulties become minimised with plantations in immediate proximity to the stock factory, and disappear so soon as the bamboo is converted into the finished paper stock, a "tow" like fibre in which condition it will press-pack-like cotton, jute, hemp, or similar articles of commerce, and be conveyed to this country at low cost.

THOS. ROUTLEDGE.

Claxheugh, Sunderland, 28th April 1879.

THE CULTIVATION OF TREES.

TO THE EDITOR.

SIR,—I shall feel much obliged by your telling me the meaning of the word "Chalkmark" as used by *Observer* in para. 2nd, line 4th, of his communication to the *Madras Mail*, quoted by you in your this month's issue, page 127.

Will the same "Chalkmark" do for the rest of the life of the tree, or must fresh ones be made every year?

INQUIRER.

TEAK SAPLINGS.

TO THE EDITOR.

SIR,—In my letter to the *Indian Agriculturist*, on the growth of teak plants and which appears in the May issue of that paper, the average height to which the plants, attained in 12 months, is put down at 6' 9" instead of 8' 9", which was stated in my original letter.

R. R. E. BROCKMAN, CAPTAIN, R. E.

Tanjore, 11th May 1880.

CINCHONIDINE AND CINCHONINE.

TO THE EDITOR.

SIR,—Have any of your readers tried the two new sulphates? *viz.* *sulphate of cinchonidine*, and *sulphate of cinchonine*, if so, will they kindly tell me through your columns with what success; at the same time, giving particulars as to doses, &c.

Both the above—especially *cinchonine*—are far lower in price than *sulphate of quinine*, and, if found as efficacious, especially with estate coolies, will prove a great boon.

EGLANTINE.

INFORMATION WANTED.

TO THE EDITOR.

SIR,—I have been advised to apply to you by the Editor of the *Ceylon Observer* for information on some subjects of agriculture. The products I propose cultivating, are as follows:—Sago (palm) Indian corn, Manioc, span trees for dye, ground-nut for oil, also cotton seed, castor seed, sesame or gingelly, poppy seed, and some plants for fibres, pepper vanilla, &c.

If you could send me or recommend any books on any of the above subjects, I should be exceedingly obliged.

B.

THE FOREST DEPARTMENT.

TO THE EDITOR.

SIR,—The letter of a Forester in your April number, has the merit of plainly expressing the writer's meaning, which is to urge that all posts in the Forest Department should be open to competitive examination, after a training at the Dehra Doon Forest School, and that no previous experience of the work in the forests should be required from candidates, and that the expense of the training should be borne by Government.

I will leave without further comment the bad taste of the writer's reference to Mr. Brandis, to whom, in the first place, the great progress made in the department of late years is due.

The Forester criticises the admission of apprentices to the Forest School whose only qualification, besides a six months' experience of work in the forest, he stigmatises as a smattering of their own vernacular. But the qualifications required in the Forest Code for apprentices are as follows :—

I. Ability to read fluently and to write correctly in their own language.

II. Arithmetic to decimal fractions and vernacular accounts. A knowledge of English is considered an advantage.

If we had there, a knowledge of land measuring, as practiced by revenue subordinates, these qualifications would seem to be all that is required for subordinate appointments in the Forest Department, when supplemented by two years' training in the Forest school.

It is, however, very doubtful whether men of the apprentice class except from Oudh or the North-West Provinces would go to the Forest school at all; and whether they cannot acquire all the knowledge necessary for a Forester's post, for which they are fitted, and not for that of forest-ranger, in their own province.

Classes for their further instruction in accordance with a system drawn up in the Forest School might be held at the head quarters of each province, in the rainy season, without interfering with the proper work of officers. As pointed out by the Forester, there is an unfairness in giving the same Forest-ranger's certificate to these apprentices, and to probationers whose intellectual qualifications are much more extended.

Men of the Forest-ranger class should certainly be trained at the Forest school, and only in exceptional cases should Foresters be appointed to this class which Government has recognised as the most important for the success of the department.

The salaries of Forest-rangers range from Rs. 50 to 150 a month, and for this pay men of considerable ability and education are always available.

The Forester asserts that the hopes of Government to induce men of good family to enter the department, as sub-assistants, are not likely to be realised.

Such men, he says, would shrink from any service, and far more from that of the Forest Department.

Only middle class men would be available, and they cannot afford to pay for their education, nor even to stay in the department six months without pay until they have shewn their fitness for the work.

But I have good reason to know that already the post of Forest-ranger is sufficiently attractive, and numerous application from educated men come in at the merest rumour of a probable vacancy.

Why, then, should such men be bribed with the appointment of sub-assistant, which should only be the reward of exceptional merit, or long service.

In Europe, men of the best families join the Forest Departments of their native countries, on stipends inferior to that of the lowest grades of Forest-rangers in India, and after a long professional training at their own expense. If men of good family here will not join the department, there is certainly no necessity to bribe the middle classes to do so, by putting them into the superior grades at the outset.

Socially, the appointment of Forest-ranger should be highly considered, as the men are classed, in the printed lists of the department, as members of the executive staff.

Europeans have been appointed at once as sub-assistant conservators, as a European training has been considered necessary, and men who possess it cannot be engaged on less terms.

The out-door work of the Department is admirably suited for a large class of Englishmen who dislike under work, and prefer the exposure and freedom, and even the hardship of the forests, whilst the 'Forester' admits that natives of India dislike the work exceedingly.

The term native of India is very vague and deceptive, and in newspaper correspondence may be taken to mean, in the East of India at least, an educated Bengali.

Bengalees are not natives of the tracts of country where forests are found, and the simple inhabitants of these tracts, not yet qualified for such appointments, would far prefer an Englishman to any other foreigner as the *jungally sahob*, who is to restrict their former free run of the forests.

In other parts of India, doubtless, a similar preference exists. Too much training for subordinate posts renders men above their work, and I have heard a Bengali Executive Engineer complain, that his subordinates from Roorki are disgusted with the simple duties they are called upon to perform. Thorough professional training of probationers, however, will always be of great value, and will give us a class of Forest-rangers and assistants, who will put new life into the executive work of the department.

But the previous six months' training in actual work in the forests is indispensable, as by this alone can the qualifications of a candidate be approved, and men unfitted for the work can thus be spared the waste of time involved in training for a department for which they are constitutionally unfitted.

W. B. F.

Dubri, Assam, April 20, 1880.

THE PRESERVATION OF SILKWORMS' EGGS.

TO THE EDITOR.

SIR,—The preservation of silk-worm eggs is a great point in these parts with sericulturists. So much so that not five per cent. of the eggs, hatched from the stock at the ensuing season. They attribute this failure to the heat of the climate, and those who have the means transport them to the Himalaya during the hot months. But a circumstance has occurred within my observation lately which makes me think that bad treatment has most to do with the addling of the eggs. The plan followed in these parts is to stretch a sheet suspended by strings and put the moths on them where they to copulate and lay eggs ; the eggs of course adhere to the cloth, and when the people collect them they disengage them from the cloth, by a spoon or knife, and I fancy wound the delicate shells which ultimately leads to the death of the embryo.

A friend of mine recently got a sheet of eggs from China. The sheet of paper was covered with eggs with hardly any spaces, showing that the people put moths down on vacancies to lay their eggs. The sheet of paper was of loose but thick texture, like native Indian paper, and came from China folded up in a long envelope. The paper had 10,000 eggs or more on it, which all hatched, the failures were not two per cent. We here received a lesson, evidently the usual way of collecting eggs was wrong, it counteracted Nature, for the moths like all insects when laying discharged with the eggs a secretion which not only glued the egg to a spot, but which also acted as a preservative of it from heat and other accidents. This order of things was disturbed by our scraping the eggs off their place of deposits and huddling them up in an earthen pot as grain in a grainary. In laying on the paper it was never found that one egg was layed on the other, but the moth moved on, so that each egg had its place without being crowded by others. We followed the China method in the egg laying this year, we have sheets of paper with eggs, and unless the paper is not of a bad kind, we have every hope of our success. The China plan was to our present thinking so rational. The sheet had been transported several thousands miles in a ship and through heat and rough treatment with no ill results.

Gugrah, April 28th, 1880. W. BUCHANAN.

SEA ISLANDS COTTON SEED.

TO THE EDITOR.

SIR,—Can you let me know where I can get Sea Island Cotton seed, or another high class of cotton seed ?

F. DE. L.

INDIAN TEAS.

(To the Editor of the Englishman.)

SIR,—I have read with great interest your article upon Indian teas, and although I agree with the comments passed upon the action of Government in the labour question, yet I think that shareholders, capitalists, planters, and others interested in the great tea industry of this country should also turn about and ask themselves what they can do to place Indian teas upon a fair basis in comparison with teas shipped from China. First, then, I would say that the brokers' charges are far too high. Brokerage, lotting, and advertising form a very heavy item in a tea sale account, and I understand that Calcutta tea brokers get two per cent. brokerage out of tea sold in this market (1 per cent. from buyer and 1 per cent. from seller), and this I consider a monstrous charge, considering the insignificant services rendered, and I would ask for what purpose this brokerage, lotting, and advertising expense is incurred upon Indian tea in Calcutta, seeing that the same charges have to be gone through with again in the London market ? Clearly, the

total cost of the same must come out of the pockets of Indian producers.

No doubt we shall be told that better prices are often obtained by sales in Calcutta. All I can say is, that such an argument would tend to prove that Indian tea-growers have really no market at home—or anywhere else—and it is this that is at the root of the present critical position of Indian teas.

Up to about the present time fair prices have been realised for Indian teas for the purpose of mixing them with much China rubbish that is brought to London, and hitherto Indian teas have been almost exclusively absorbed in the London market for mixing purposes.

We shall perhaps be told that the British public would not drink Indian teas, and we will admit that certain pungent teas would not be suitable, but on the other hand the public at home have never been allowed to test the merits of Indian teas, except to a very limited extent. It is generally admitted, I believe, that Indian teas are far superior to the China article, independently of their greater purity, and what is really wanted for our Indian teas is *a market free from the tricks of trade.*

The planters in India should co-operate with the consumers at home, or at all events they should at least insist upon having Indian teas placed before the public, and a company could easily be formed for that purpose in London, having agencies in every town and village in the United Kingdom.

There can be no doubt, I think, that if the poorer classes were allowed the privilege of drinking Indian teas of fair flavour and strength, they would at once appreciate them, and it would be doubtful indeed if they would ever care again to touch the *China mixtures.*

The poorer people at home are buyers of high class teas.

Indian teas are admittedly superior to China, yet the fact remains that up to the present moment no one in India has yet shown himself equal to the great industry, no one has come forward to direct this industry into a proper channel of its own. Look at the prices quoted in the Calcutta sales of the sixth instant,—six annas—equal, in English money, taking exchange into account, to about seven pence.

Thus 7*d.* for tea, duty 6*d.*—total 1*s* 1*d.*—yet such teas cannot be bought at home for less than 3*s.* or 4*s.* 6*d.* per lb.

Why should not the planters come in for their honest share of the profits?

PEKOES.

THE DRYING OF TEA.

(To the Editor of the Englishman)

SIR,—Under date of 10th February last, Mr. Eugene C. Schrottkey, I observe, addressed you upon the subject of the non-keeping qualities of Indian teas of the present day as compared with their China rivals, and he suggests that there is a danger of increasing this defect by drying the teas with heated air instead of charcoal fumes.

Now without going into the subject of the antiseptic properties of the fumes from charcoal, I would ask a little of your space to draw attention to the well-known fact that "Green" teas keep quite as well as black teas. Exposure to moist atmosphere after a chest is opened does deprive green tea of its "bloom" a little, but its strength and pungency remains undeteriorated quite as long as with black tea under similar circumstances.

But green tea never knows the fume of charcoal throughout its whole course of manufacture, as it is dried over pans (usually iron) of graduated heats.

This, I think, conclusively shews that the keeping qualities of teas are not due in any way to the antiseptic properties which Mr. Schrottkey attributes to the fumes of charcoal.

In former times (10 or 12 years ago) Indian teas had not the character of deteriorating by keeping, but at that time it was customary to subject the leaf, during the process of manufacture, and while in the moist state, to roasting in pans, thereby raising its temperature to a very high degree, and while it was at this high temperature it was re-rolled to ensure the juices being all thoroughly subjected to the effect of the heat. *The object of this process is analogous to the process of raising to boiling point, vegetables, or fruits in syrups, before being hermetically sealed in cases or bottles.*

The high temperature renders the fermenting agents contained in the juices of the leaf completely inoperative, as may readily be observed by subjecting the leaf, while green coloured, to this roasting process, after which no matter how long the leaf may be kept in balls, even in the moist state, fermentation cannot again be perceptibly induced.

The roasting process has, however, been very generally abandoned with Indian teas, since about the year 1869; but China teas are still subjected to it in their manufacture, and herein, I believe, is to be found the true cause of the comparative non-keeping qualities of Indian teas of late years.

It is almost impossible, over charcoal fires, to give the leaf such a degree of heat as it can be subjected to in the pans while it is moist without liability to burning, for charcoal fires are so difficult to regulate that one time they will scorch the leaf if "forced," and then as readily die down again if not extra carefully attended to.

In this respect drying machines, in which hot air is used, have, I believe, an advantage over charcoal fires, because with the former the tea can be subjected to a high degree of temperature without the same risk of that degree being exceeded suddenly or unexpectedly. The entire teas of only a very few estates have as yet been dried by heated air, but those during last year which were so dried (notably Burkhola teas) have kept well and earned a good reputation for freshness of flavor with the trade here.

S. C. DAVIDSON.

Belavon, Strandtown, Belfast, 7th April 1880.

TEA DRYING.

(To the Editor of the Englishman.)

SIR,—In your issue of 4th instant I see a letter from Mr. S. C. Davidson, the inventor of the "Sirocco" tea drying apparatus, anent the drying of tea. I am very glad that he has brought forward the case of manufacturing green tea (which is never submitted to charcoal fumes) against Mr. Schrottky and others, who think that there are antiseptic qualities in charcoal fumes which are necessary for the perfect preservation of tea.

For some years I manufactured green tea, and, in the manufacturing processes of black tea, very strongly advocate the disuse of charcoal where it can be done economically. But, in my advocacy, it did not before strike me to bring in the case of the green tea, which, I think, is an argument that can hardly be gainsaid.

However, in searching for the cause which has given, unfortunately, the non-keeping character for the last year or two, to some of our Indian teas, I think Mr. Davidson also overshoots the mark, and I doubt if the reason he assigns will bear scrutiny. I am not quite sure what he means by fermentation, but it is very well known that tea leaves, subjected to the roasting process which he describes, will become *sour* if not as soon, very nearly so, as leaves which have not undergone that process. I have often proved this before discarding the roasting pans, and any one can soon satisfy himself as to its accuracy. And it is also a significant fact that, when roasting was the rule instead of as now it is the exception, far more sour Indian teas appeared in the London market. Sour teas are now hardly to be found.

I do not believe that any antiseptic is required in tea manufacturing, and I have had a considerable number of years' experience with rather considerable quantities of tea. I have also had a good deal of correspondence on the subject of drying in which appeared a great deal about antiseptics. But this word was, on a particular occasion, excluded for a more familiar one (I suppose to make certain, in case I should not possess a dictionary), and I was told to take great care that the "curing of the leaf" was properly attended to. This pulled me up, and my mind's vision would not resist bringing up salt herrings and Finden haddocks! And I thought, well, surely, if some sort of salting is required, a chemical could be found which would be cheaper and cleaner than having to burn charcoal in our tea houses.

And now I will venture to suggest a reason which, I think, is quite sufficient to explain why some Indian teas have lately acquired the non-keeping character. Within two or three years there has taken place a great change about "pakka-bhattying" and packing. Some people are in such a hurry to get the tea into the box the day that it is manufactured that one would think, as my imaginative friend said, it should be packed the day before! Generally speaking, it is practically impossible to manufacture leaf and have it packed the same day, yet many strongly go in for it, or, at least, say they do. In former years, 10 or 12 or 15 years ago, pakka-bhattying was a long and tedious process, about 12 hours being generally thought necessary to thoroughly desiccate the tea and make it fit for packing. Now, in these latter years, half an hour, or a few minutes, is thought enough to thoroughly dry tea and make it safe for packing. And here, I believe, is principally where the evil lies. Tea may appear perfectly crisp and dry after a few minutes firing, but, on careful examination, it will be found that it is not dried to the core. And though I think that the old system of pakka-bhattying may have been needlessly long, as a rule the present system is inclined to the other extreme. The old gentleman who taught me tea-making was most particular with the pakka-bhatty, and used to crack pieces of tea between his finger and thumb close to his ear, and bite bits, all to make sure that not a particle of moisture was left in the tea before he would allow it to be put in a box.

I know that arguments could be brought up against this explanation of mine, such as that the tea would go bad in the box on transit, and that the non-keeping character exhibits itself in the grocer's shop only, &c., &c. But it would be encroaching too much on your valuable space to combat these objections, and I would only now beg to recommend that

planters look carefully to their pakka-bhattying, and see that the tea is thoroughly dried before it is packed, and soldered down properly. If these things are well attended to, and the tea placed in the market free of moisture, I am satisfied that we will hear no more of Indian teas developing non-keeping character.

And, Mr. Editor, I would beg leave for just another word. I thoroughly believe in the Sirocco and in its working, as being an excellent and economical tea dryer, and would use it exclusively, but, eh man, its ower dear in these hard times.

NEWOTHA BILL.

Cachar, May 10th, 1880.

TEA DRYING.

TO THE EDITOR.

SIR,—Some correspondence which appeared in the *Englishman* on this subject, induces me to re-affirm in a more terse manner, what I have already said on this matter.

1. Complaints regarding the non-keeping qualities of Indian teas (more particularly Assam and Cachar teas) have been frequent of late, and were first made after drying directly over charcoal had been abandoned to some extent in favour of drying by heated air, not containing charcoal fumes.

2. These complaints have been supported by actual experiments made by scientific observers in England and on the Continent, and considerable weight must therefore be attached to them.

3. Such complaints had not been made previous to the introduction of tea-drying apparatus, doing away with the use of charcoal.

4. The fumes of charcoal possess certain well-known antiseptic qualities, absent in mere heated air.

Question arises :—

Is the loss in the keeping qualities of Indian teas (recently complained of) due to the now extensive abandonment of drying directly over charcoal, and to the use of tea drying apparatus not imparting to the heated air the same or similar antiseptic qualities which charcoal fumes are known to possess?

In the absence of evidence to the contrary, probabilities strongly point to the affirmative.

Mr. Davidson and the able writer in to-day's issue of the *Englishman* would answer it in the negative referring to the keeping qualities of green tea, which is dried in pans, and comes not in contact with any antiseptic fumes.

But I would venture to remark that no discussion, however able will clear up the point at issue. Positive and scientific evidence can alone dispose of it ; and I would therefore suggest that a series of samples of tea, manufactured under precisely the same circumstances, but dried, one series directly by charcoal fumes, the other by heated air not containing such fumes, should be submitted to some scientist at home. Thus alone, in my opinion, can this question be solved.

The reference to green tea does not bear on the point at all. Green tea has not gone through the same fermentative process, and its keeping qualities can, therefore, not be compared to black tea. Any organic substance that has once undergone a process of fermentation, though the same may be thoroughly checked at any particular stage, is, on the slightest provocation far more disposed to decomposition or further fermentation, than any other similar organic substance which has not undergone previous fermentation, but has simply been dried, as is the case with green tea.

The drying over charcoal has been necessarily abandoned in a great many tea gardens, but in case the above question is answered in the affirmative, science will tell the tea planter how to impart antiseptic qualities to the drying air that has been heated by mere contact.

EUGENE C. SCHROTTKEY.

Calcutta, May 18th, 1880.

INDIAN TEA *vs.* CHINA TEA.

(*To the Editor of the Englishman.*)

SIR,—The remarks in your to-day's issue on the extract you quote from the Melbourne *Daily Telegraph*, are very much to the point, but the misapprehension you refer to, *viz.*, that of Indian teas being more expensive to the consumer than China teas, is, I think, even greater than you have shown. The Indian teas which are higher in price per lb. than China, are of better quality in other respects than that of merely going further. That implies mere strength. They are more pungent than, and have (in Darjeelings and Kumaons at least) a superior flavor to, China teas. This all round superiority leads me to urge the following considerations on those interested.

The fact must be faced and not ignored that a cheap but very inferior China tea is the ruling article in Australia, and that, for years to come, it will, in some form or other, continue to be so. To attempt to revolutionize this state of things at one blow, would be to raise up all manner of opposition on the part of the Australians themselves, and to court failure. The consumers and grocers must be enlisted on the side of Indian tea and not be arrayed against it. To do this and still gain our object, it seems to me that a double set of operations should be carried on simultaneously, *viz.*, (1) Give the Australians a tea suitable for mixing with China tea, and (2) send them a blended Indian tea ready for use. This would be a combination of sapping and mining with the blow direct, a succession of which operations from year to year would in time give Indian teas the first place. I see no good reason why this should not apply to London as well as to Australia.

It is an acknowledged fact that the Indian teas best suited for mixing with Chinas are least suitable for drinking by themselves.

No doubt there are mixers in Melbourne as elsewhere, or if there are not, it might be worth the while of the Representative of the Calcutta Syndicate either to do it himself on behalf of his employers, or to put the dealers there " up" to that very profitable branch of the trade.

MATT. DREWS.

May 12, 1880.

MR. ROBERTS' CINCHONA CALISAYA TREES.

(*To the Editor of the Ceylon Observer.*)

DEAR SIR,—You have made me say that the Calisaya trees grew on Pooprassie, while I distinctly wrote that they grow on Lemagastenne. I would ask you to correct this, as it is well known that the lowest portion of Pooprassie is over 3,000 feet, and I consider that the low elevation these trees grow and thrive at is the important feature in the analysis. As to their origin I cannot say ; I am told that they were planted by a Mr. Peries in 1872, who then opened Lemagastenne, while he was conductor to Mr. Agar of Wavendon and Poojagodde, from whom it is understood Mr. Peries got the plants.—Yours faithfully,

J. A. ROBERTS.

Pooprassie, 26th April 1880.

[Perhaps Mr. W. Agar will help us to trace the origin of the trees.—ED., *C. O.*]

ANALYSIS OF CINCHONA.

(*To the Editor of the Madras Mail.*)

SIR,—In reference to the enquiry about the analysis of the cinchona grown in the Papanassam Hills, I send the following copy of a letter addressed to Messrs. Jenkins and Phillips, which gives the required information.

Yours, &c.,
CINCHONA.

DEAR SIRS,—The following are the results of our analysis of the Government red bark grown at Papanassam :—

Quinine Sulphate	... 2· 6 per cent.
Cinchonodine Sulphate	... 3·21 „ „
Cinchonine Alkaloid	... 1·01 „ „

This is the finest yield of quinine from Indian red bark not renewed, we have ever seen.

Yours truly,
(Signed) THOMAS WHIFFIN.

Battersea, 8th December 1879.

THE OPIUM TRADE OF BOMBAY.

(*To the Editor of the Times of India.*)

SIR,—Your contemporary's leading article of Friday is a clear example of how a public writer may, on a point of fact, be "at sea" sometimes. The drift of the writer's argument appears to be that with an empty treasury the Government are blind to their interests in allowing the Central Indian ryot, or middleman, to amass colossal fortunes in the way they are now doing by the profits of the opium trade, and thereupon he chivalrously jumps up and suggests that the duty on each chest of exported Malwa opium be raised from seven hundred to nine hundred rupees, which he calculates would bring in a fabulous amount of revenue to the Government. All practical, sensible people, engaged in the opium trade, know full well that were an average taken of the revenue derived by Government from the duty on opium for years past, it would be found that in proportion as the duty was raised the revenue fell, for the simple reason, that this increased taxation only hampered the trade and prevented traders in the drug from operating on a large scale. This will appear still clearer when we come to see the large business done in Patna and Benares opium as contrasted with Malwa,

owing to the first named descriptions not being so heavily taxed. Then when we come to look at the place now taken by Persian opium in the China market—how that in quality it is little, if at all, inferior to Malwa,—for the reason that it can be laid down in China at about two-thirds the price of the Indian drug—when, I say, these facts are borne in mind, would it not be folly on the part of the Government to think of raising this already excessive, and almost prohibitive duty on Malwa opium, and thereby cutting at the very root of a trade which is the source of so large an income to the State?—Yours, &c.,

GOPALLDASS LADDOOWALLA.

ON THE ERGOTISATION OF WHEAT DURING THE YEAR 1879.

(*To the Editor of the Lancet.*)

SIR,—The peculiarly sunless year of 1879 has, amongst other things brought about an amount of ergotisation in the wheat crops that is, as far as I can learn, quite unprecedented. With the details of this subject I will not trouble your readers beyond mentioning the fact that the absence of sun favours the production of ergot in wheat in two ways—first, by making the wheat late in point of time in flowering, so as to approximate the flowering of the wheat with the maturation of the Claviceps sporidiæ more nearly than usually happens; and secondly, by retarding the process of fertilisation of the wheat, for it is at this time that the ovule becomes affected with the ergot-producing fungus. I have examined several samples of last year's wheat, grown in the vicinity of King's Lynn, and have found almost all those which were grown in the marshland or fen district contaminated by a considerable percentage of ergots, some more and some less. Upon the health of the general public I believe this will have no appreciable effect, because of the large quantity of foreign corn consumed by us. But in certain districts it is the custom for the labouring families to live a great part of the winter, at any rate as long as it lasts, upon the corn gleaned by them during the harvest, which they have threshed and dressed for themselves in the most primitive manner. In many of the samples I have seen that have been threshed and dressed by the most improved agricultural implements, a great number of ergots were not removed, so that a family subsisting for several weeks upon corn gleaned from a district in which ergot is abundant this year, and which had been threshed by a flail and winnowed by a current of air, would stand a poor chance of escaping some of the constitutional effects of ergot.

From the conversation I have had with agriculturists upon this subject, they one and all ignored the idea of these foreign bodies being ergots at all until they were demonstrated to them, the little black bodies being mistaken for the excreta of birds or of rats or mice. Not being aware of the presence of the ergots, nor of their poisonous nature, many samples find their way to the miller in a condition that the farmer could very considerably improve by more careful dressing.

Your obedient servant,

CHARLES B. PLOWRIGHT.

King's Lynn, Feb. 16th, 1880.

THE JACK FRUIT TREE.

(*To the Editor, Mysorean.*)

SIR,—Allow me kindly to answer the query of your correspondent regarding the quality of the fruit of transplanted Jack (Artocarpus Integrifolia.

If the practice of growing this tree should anywhere be sound in principle, it must be in the Mulnaud, where the best kinds are grown and where the fruit, I estimate to form about 1-20 of the total food of the population. The tree is as common in the Mulnaud as the Bannian and the Arié (Ficus Bengalensis and Ficus Religiosa) are in the midan.

The following is the mode of growing the tree as practised in the Mulnaud. Well selected seeds are buried in a basket containing earth and ashes in equal proportions, and watered until they germinate, and are then removed to nurseries, where they are well looked after till about a year, when they are transplanted into pits, dug in places where they are intended to stand. The best season for transplanting is the early part of June.

Two kinds of fruits are known.

Yours truly,

Teothahally, 30th April 1880. J.

THE DELHI GOLD FIELD.

(*To the Editor of the Delhi Gazette.*)

SIR,—The Indian Government, the Secretary of State for India, and the British public, now admit that auriferous quartz reefs, not only exist in the Madras Presidency but are found to be rich in gold.

I believe it is a well-established fact that crystalline and crystallized quartz formations almost as a rule contain gold, and the presence of detached pieces and blocks of rock crystal, or crystallized quartz indicate that a quartz reef must exist somewhere in the vicinity, from which they have been separate.

I shall show presently that in the vicinity of Delhi ancient mines exist, from which lumps and blocks of rock crystal have been obtained, and as the supply is by no means exhausted, it follows that scientific examination of the locality will lead to the discovery of the parent quartz reef, and if that does not prove to be metalliferous as well as auriferous, a geological phenomenon will result.

So certain am I that a grand gold field is to be found for the seeking, at no great distance from the City of Delhi, that I have purposely kept back this paper, till the fall of Ghuzni was announced, and as that event has taken place reticence is no longer necessary. Further, as the Afghan war will not soon be over, and will require a very considerable sum of money to carry it on, the gold needed may, and I hope will, be drawn from the valley of Aurangpur.

The information given beneath is taken from Doctor Thompson's Report on the rock crystal mines, and was published in the *Punjab Gazette* at a time, when the existence of gold bearing quartz reefs in India was not known and our knowledge of crystallized quartz reefs and their value was yet in its infancy.

Dr. Thompson states:—The village of Aurangpur is situated in a small valley, surrounded by wells, and the road leading to it from all sides for a distance of three miles at least from the village, is impassable to any but foot passengers and cattle from their rocky and precipitous character. The mines themselves are situated about two or three miles, to the south-west of the village, and can only be approached by paths like those just described.

The crystal does not occur in its primitive position but in a secondary deposit of siliceous breccia very highly impregnated with iron, each crystal is encased in a sheath of hæmatite.

The deposit of crystal occurs in a small valley or basin among these hills, about two or three miles to the south-west of the village of Aurangpur. The valley is about five hundred yards long and from fifty to one hundred yards broad and dips toward the north, the only part of the deposit which has been worked is the south end.

The works have hitherto been carried on in two ways: first, open pits gradually sloping downwards; second, by wells and shafts. Of the former there are two, neither of which have been worked for many years. Neither is deeper than twenty feet from the surface. Of the latter there are three, the deepest of which was sunk by the late Raja of Ballabgurh, and is twenty feet in depth and about ten feet in diameter. From the bottom several galleries extend for a short distance, on all sides. The two wells are of much less depth.

The strata through the deepest shafts are not uniform, for more than the first half of the depth at first they are the same as I have described and highly ferruginous; subsequently the rock begins to lose the irons and a short way down is composed of small pieces of pure quartz, embedded in a matrix of almost pure white clay. I have not been able to ascertain in what way the crystals occur in these beds, but the *Lumbarders* of Aurangpur inform me that, it is here the largest and purest specimens are found. In the upper ferruginous beds, are layer, of red clay, which I consider originally to have been *Kaolin*, and subsequently impregnated with iron. In the upper strata many of the crystals are tinged with yellow from an admixture of iron.

At page 47 of "Punjab Products" it is stated that the rock crystals exhibited, were obtained from a place (? village) called Bhur, in the district of Goorgaon.

I have heard it stated that occasionally very small quantities of *gold dust* are discharged by the water of the *Sona* hot sulphur springs. Now *Sona*, is sanscrit for gold, whilst the *Gundhuck*, is the name for sulphur consequently some valid reason must have existed, in ancient times, for giving this very significant name to the sulphur spring.

The rocks and clay described by Dr. Thompson are evidently connected with a quartz formation, and as the small pieces (*crystals*) of pure quartz, have a history of their own, the deepening of the Rajah's shaft from 20 to 60 feet would throw considerable light on the subject, and if it be true that the *Sona* sulphur spring has thrown off gold dust (no matter how small the quantity), we have reliable evidence of an abundant deposit of crystalized quartz in the neighbourhood, and all but reliable evidence of the existence of gold in its purest form.

The season is now too far advanced for any *prospecting* to be undertaken, but in the mean time the rocks at and about "Sona" might be explored and a sharp look out kept for the smallest quantity of gold-dust to secure which, three or more sheep skins with the wool on should be so placed as to catch the water, as it issues from the spring.

In October Aurangpur will, I hope, be visited by professional men from the Madras gold field, and their practical knowledge will very soon lead to the finding of Delhi's auriferous quartz reefs.

DOUNSAL HALL.

Kotegurh, 28th April.

SERICULTURE.

To the Editor of the Delhi Gazette.

SIR,—I see by your columns that sericulture is attracting a good deal of attention in the Doon. My experience in that line may be of service to those interested. It may not be generally known that the Maharajah of Jummoo has a large silk factory, and that a Mr. Halsey has one at Puthan Kote; they have both been very successful, but I don't think it would prove a success in the Doon, as January being the month in which they are generally bred, I fear the temperature of the Doon would be rather severe in that month, and the worms would perish. Eggs can be procured at Lahore, and the easiest way to breed them would be a long building ventilated from the top with two doors, the longitudinal side of the building having tiers of shelves; the building should have a drain inside constantly filled with water to prevent vermin finding their way to the worms. About the 15th of January, or when the young mulberry leaves appear is the time for breeding, the eggs are exposed in paper trays to the sun, and in half an hour or so the worms appear, when they should be carefully put on the shelves which should be lined with paper, and fed with the young leaves of the mulberry. In about ten days they are strong enough to be handled for the purpose of cleaning the shelves, when they should be well supplied with leaves. In about thirty days they are ready for spinning, when light branches should be thrown on the shelves, and they should be left undisturbed, and as they finish the cocoons it should be removed and put into hot water to destroy the chrysalis except those that are required for breeding, which should be put away separately. When the butterfly will appear and commence breeding, the eggs should be carefully collected and kept carefully in a dry place for next year's breeding. The main difficulty is the unwinding of the cocoons, but I am inclined to think the hand reel used in France which could be procured would be the easiest and the cheapest as native women could be taught to unwind it. About 2,000 cocoons produce a pound of silk. I would be very happy in assisting any party desirous of trying the experiment in getting up a Joint Stock Company, but I think Saharunpore would be a good locality, the mulberry leaves might be procured by contract from the adjoining villages and hereafter the company could plant their own mulberries. There is little doubt but that the silk would meet with a ready market, and if the native women could not be taught to unwind the cocoons, there are plenty of poor Eurasian women and girls who would be glad to undertake it. The cocoon can be kept any length of time, so long as they are kept from damp, and unwound at any time. I would be glad to afford to those interested any further information.

PHILO.

THE JACK TREE.

To The Editor Mysorean, Bangalore.

SIR,—A writer to the *Indian Agriculturist* asks whether the Jack will bear transplanting, and says that he is informed by the natives that it will not. I can assure him that he is mis-informed. The Jack is extensively used on the lower slopes of the Neilgherry Hills and in parts of the Wynaad as shade for coffee, for which purpose it is admirably suited. Jack seed is planted in nurseries, and when the young plants have attained the height of about 12 inches, they are planted out between the coffee. On the Droog Estate I have seen the seed planted out in bamboos. The latter are cut into lengths of about a foot, and the tube filled up with rich loam into which a single jack seed is dropped. The lengths of bamboo are then buried in an upright position and watered in the usual manner. By this arrangement the roots are not disturbed in transplanting as the bamboo takes some time to decay. The roots find no difficulty in making their way through the bottom of the bamboo which in time moulders away.

A writer in the *Madras Mail*, the other day asserts that all Jack trees will bear fruit under ground, when aged. This I think is a mistake, as I have seen a tree in its fifth year bear fruit under the soil, and I have known many trees 20 years and upwards that showed no signs of fruit on the roots. The Burmans say that they are two different varieties, in fact they prize the kind that produces fruit at the roots, and such fruit sell at from 3 to 4 times the rate of the other.

Coonoor, 15th April 1880. PLANTER.

SOAKED *versus* BOILED GRAM.

To the Editor of the Madras Mail.

SIR,—With reference to the question put by your correspondent "R. R. E. B." in your issue of the 20th instant, on food for bullocks, I beg to state that horned cattle generally thrive and fatten much more quickly on raw than boiled horse gram, *Cooltee or Dolichos uniflorus*, and I have never known anything go wrong with cattle so fed. The only inconvenience if any that occurs, is that some animals will pass out a small portion of the gram undigested with their dung, and the gram so passed out being perfectly sound, will readily germinate if planted. To prevent this the gram should be broken up in an ordinary stone mill, such as is used for grinding raggy or other grain, or it may be pounded in a mortar, and be then steeped in water to soften, as is done to chunna or Bengal gram when given to horses. By breaking up the gram it will soften the more readily when soaked, and be better realised by the animals to which it is given. Cattle unaccustomed to eat gram will have to be coaxed to take it for a few days before they partake of it freely.

Yours faithfully,

Ercaud, 24th April. JOHN SHORTT.

MINOR REBOISEMENT IN THE PUNJAB.

(Communicated.)

SIR,—Professional business has necessitated my being obliged to traverse a good many square miles of country to the north of the town of Attock and to the west of the river Cabul—which at present is very barren and treeless, excepting in the immediate neighbourhood of the villages where a few trees still exist—and it has been a continual source of wonder to me, that the local authorities do not induce the zemindars to plant trees along the beds of the natural and artificial watercourses within their respective village bounderies.

Judging by the emerald colour of the grass on either side of the watercourses the ground must be in a very fine state of moisture and well fitted for the reception of trees that delight in moist situations, such are the Salicaceæ in particular; then we have the *shisham* (sissoo), *siriss* (siriss), *chinar* (plane), *tút* (mulberry), and many other useful trees which I need not here particularise, as they are too well known, or ought to be, to the local authorities.

The villagers have a lot of spare time on hand during each cold season, which could be turned to great advantage to themselves, the country at large, and the Government, if the latter were to use a little gentle pressure to induce the villagers—at the above-mentioned season of the year—to spend, say, half of each day in planting out, along the natural and artificial watercourses, some useful seedlings, which could be sent to them from the Saharunpore gardens, and from the Agri-Horticultural Society at Lahore, besides obtaining some few in the immediate neighbourhood of the few and small copses nearer home.

The ultimate benefit is to the villagers, as they would obtain the thinnings, loppings, and eventually the fallings of the mature trees as it became necessary to cut them down to prevent them from overcrowding one another.

I have seen the emerald grass, before written about, as far as thirty feet from the watercourses, showing what a large belt of arborescent vegetation could be raised along them with a little trouble in planting and keeping the cattle from grazing there for three or four years, or until the trees are old enough and tall enough to be beyond the reach of anything but wilful damage.

Villagers club together to cut an irrigation channel: Why should they not club together to plant belts of seedlings along those irrigation channels? and also along natural channels within the limits of their villages? The one (irrigation channel) is of equal advantage with the other (arborescent belt).

With the watercourses shaded by trees less evaporation would take place, and their irrigation water would supply a greater area than at present.

Other benefits in connection with tree-planting I need not mention as they are too well known.

Let the local authorities see what they can do in this matter in the ensuing cold season.

The "luar" (a tecoma), with its handsome orange-gold flowers, is now in blossom: so also the "gandere" (wild oleander), with its pretty bunches of pink flowers: the "siri" (siriss) with its white silky-looking flower, having a pleasant scent: the "kikar" (acacia farnesiana), and its yellow flowers nicely scented: mulberries "tút" are ripe and in great profusion, and are greatly eaten by the people; the fruit tastes rather mawkish: the "shisham" (sissoo) is already seeding: so the "verma" (rhazya stricta): the "zoz" (camel-thorn) is in flower.

Barley and wheat cut, about a 13 annas crop: ground being prepared for sowing Indian-corn, joar, and bazri: onions grown in large quantities, being irrigated and weeded.

Grapes filling out: pomegranates the same but more slowly, strawberries were a failure.

In the Pitelian garden onions are being cultivated, also gourds of sorts: peas obtainable in small quantities.

Food grains continue high in price, due to the circumstance that every spare ounce is bought up by the Commissariat agents for the use of the Army gone to fix the "Scientific Boundary" between Russia and England.

Kund, April 28, 1880. G. P. P.

The Indian Agriculturist.

CALCUTTA, JUNE 1st, 1880.

CHARCOAL *versus* HEATED AIR.

WHEN a subject like this comes before the public, and more particularly before that section of the public most interested in its careful discussion, we should think that the consideration of the entire question would be faced with the utmost desire to arrive at such facts and deductions as might reasonably be expected to conduce to a proper solution of the difficulty. Such has not been the case with this disputed point, and the whole discussion has been carried on in the various newspapers by a series of assertions more or less dogmatically made, but without any attempt to prove one of them either by a reference to experience or by logical reasoning. In one case a contemporary resorted to what might be called a quibble to assist in upholding a theory, and denied that charcoal, *viz.*, pure carbon, had any antiseptic properties. Surely it was well known that the term "charcoal" in this discussion was never intended to mean "pure carbon," but the common charred wood as used by planters under the general name of charcoal. There are unfortunately plenty of corners in this important subject on which to hang arguments, without having recourse to such a mode of meeting the views of an opponent. We will state the question clearly and in such a manner that no doubt need exist as to what is meant. We are not wedded to either side of the argument, although in common with every one who has studied the subject, we have our own opinions on it, but these being only theoretical, and to a very limited extent borne out by inductive reasoning, we are unwilling to adopt either side in the discussion, until the whole matter is made the subject of such a series of experiments as will leave little or no room for doubt. No amount of theory is worth a few fairly conducted experiments, and we have repeatedly asked that some planters in a position to do so, should submit the question to the test of such experiment. We shall first state the arguments *pro* and *con*, and then describe the nature of the experiments we would recommend. We may premise that it seems taken for granted that there is no room for dispute as to the drying properties of heated air, as used in the various machines applied to this purpose on the gardens, that the heat engendered does its work of drying pure and simple, as well as is done by the *dhools* and the charcoal fumes, but we shall have to take up this subject also, as we do not accept the assumption as proved.

Those, then, who argue in favour of charcoal fumes, submit, that apart from a more efficient drying, the tea is "cured" by the fumes of the charcoal being compelled to pass through the tea which is placed over the *choola*, the heat and fumes being prevented from escaping at the sides by the basket work of the *dhool*, which is lined with paper. There does not seem to be any dispute about these fumes possessing antiseptic properties generally, the question at issue is whether these are absolutely essential for the purpose of manufacturing a tea which will keep. Now, one powerful argument in favour of the curing properties of this charcoal heat is the fact that the Chinese have never used anything else for the purpose. The earliest records connected with the industry in that country, show that the tea has always been dried with charcoal fumes, exactly as it is to-day. It is no answer, say those who are in favor of charcoal, to tell us that the Chinese are a conservative race, and never change anything, because we find that while this may be true in a general way, it is not true of the Chinese agriculturists. We find that they have always been the first in adopting every new plan that promised the cultivator a better crop; and the result of all this is, that in China we have perhaps the most advanced cultivation in the world, and it is a fact well known to all, that the China tea merchant and manufacturer has only to know the wants of Western Europe, to adapt himself and his modes of doing business at once to suit them. Yet in all these centuries, he, with his proverbial ingenuity, has not been able to find anything better than charcoal fumes for drying tea. Another argument used is connected with this, and it is, that the complaints made in London about tea not keeping, do not apply to China tea, but only to Indian. Now, as we have said above, the China tea-maker sticks to charcoal. Then the third argument in favour of charcoal seems to us a particularly strong one. The complaint against the keeping qualities of Indian tea is a new one, and is contemporaneous with the partial adoption of drying by machinery. Still, though this seems to us a very powerful argument in favor of charcoal, it is at best a presumption, however strong it may be. These are the principal arguments advanced by the advocates of charcoal, and when we look at the other side, we cannot say the presumptions are so strong. The advocates of machine or hot-air drying simply deny the curing properties of charcoal, and affirm that tea properly dried will keep, whatever may be the process of drying: all that is essential is that it should be thoroughly dry. Now even if we drop the antiseptic idea for the nonce, and confine ourselves to the mere question of drying, the charcoal advocates say that the machines do not dry the tea thoroughly. And again they give a reason for the faith that is in them. They say that the tea is forced into a state of dryness, and that while it is to all appearance perfectly dry, it is in reality only dried outwardly—in the same way as a roast of beef may be perfectly cooked on the outside, by an over-brisk fire, while the centre of the joint may be comparatively raw; whereas a slow fire will cook it thoroughly throughout. In the same manner when a piece of toast is being made, if it is desired to have it thoroughly crisp, a very hot fire must be avoided, and a slow one used. On the other hand, the machine advocates advance three objections to charcoal drying, which all must admit to be real. The first is—the length of time which the operation takes. Exactly. The object is to dry the tea thoroughly and make it perfectly crisp, and hence it is done slowly, the heat of the charcoal fire and the other concomitant arrangements being admirably adapted to that end. A second objection is—the price of charcoal. It is costly and about one cwt. is required for every maund of tea made; and in a district like Cachar or Assam, where the primitive forest is fast disappearing, the price of charcoal must necessarily be rising. A third is—the difficulty often experienced in getting it at any price. These are fully admitted, but are not considered enough to counterbalance the advantage which is said to be given to the tea by the use of charcoal fumes.

Such, then, is the case, for and against. It will be seen that we lean to the use of charcoal, but we are not so wedded to our opinion as to be dogmatic. We simply affirm that until the subject is finally disposed of by a series of actual experiments, the presumption of evidence is in favour of the use of charcoal. A letter to a contemporary suggests a care-

ful experiment, and the results to be placed in the hands of a practical chemist for analysis. We do not think this would settle the matter, the results of analysis being so very unsatisfactory,—as we have seen in cases of the analysis of different soils, and the evidence of chemical experts at criminal and civil trials. Most of us remember the case in which it was sought to be proved that certain mildew on cloth was caused by tar from the wrapper and not from the sizing in the cloth, and how one set of chemists proved seemingly satisfactorily that it could only have been caused by tar, while the others were as clearly convinced that nothing but the sizing could possibly have produced it. We would prefer the test of actually keeping experimental samples, in the ordinary way, in order that they may be submitted to the test of actual use in the self-same manner in which the great bulk of tea is kept. What we would suggest, then, is this. Let a planter manufacture say 500 lb. of tea; let it all be made in one break until the final process is reached; then let it be exactly halved, one moiety being finished by machine drying, the other by the old charcoal *dhools*. Let the tea be packed at the same time, taking care to mark the charcoal tea differently from the other. These two samples, which would probably amount to three chests of each sort, should then be forwarded to Calcutta in one invoice, and at once sent to London. There they should be placed side by side in an ordinary warehouse, and kept carefully from the influence of damp. In fact, let the tea be treated exactly as an average chest is treated, opened for sampling, and closed in the usual way. Let the chests lie undisturbed for two or three years, and then have them opened in presence of a committee who shall be qualified to test the results in every possible way. Let this experiment be tried by, say, eight planters, situated in different parts of India. Experiments of the same nature might also be undertaken to ascertain the effects of under-fermenting, as practised in the manufacture of "rasping" tea. We feel convinced that one cause of tea not keeping will be found here. The fermenting process is checked at too early a stage, and it is well known that if an article is once submitted to fermentation, and the process not completed, fermentation will be resumed on the slightest opportunity presenting itself. It is no answer therefore, to the advocate of charcoal fumes, to be told by the opposite party that green tea is never dried by charcoal fumes, and that it keeps somehow. We all know perfectly well that the bloom so necessary to the appearance of green tea is extremely liable to wear off, and leave the tea with a nasty appearance. The fading of this bloom is a sign of damp, and would be fatal to black tea, but is not so detrimental to green for the two following reasons. If green tea is not dried by charcoal, it is most thoroughly dried by panning, and no one who has made green tea properly can fail to be aware of the excessive amount of roasting and drying it gets in this process. Again, green tea is not fermented, and hence is not so liable to be affected deleteriously by a trifling amount of damp.

EDITORIAL NOTES.

THE Bengal Government is taking the proper means of encouraging mule breeding. We observe that they are prepared to provide donkey stallions gratis, and this, we suspect will be the entire cost of the experiment to the Government. It is a great mistake to make these and similar experiments partake of an eleemosynary character. The providing of these animals gratis cannot be said to do this, as this is a thing which villagers could not well do for themselves, however willing they might be. The wisest regulation in connection with this remains to be noticed, and it is this. "Government will hold no lien on the mule produce." This is a wise concession. Having helped towards the production of the mules in the manner above mentioned, the Government might fairly have a lien on the produce; still, we think they have acted wisely in leaving the purchase and selection of Government animals to free trade and the ordinary operations of demand and supply. After a few years, when mules become more plentiful, Government will be able to get all they require by purchasing in the usual way in the open market. As we have said before, the natives of India are conservatives of old habits, but whenever such interfere with profit, the old habits go to the wall. The knowledge that the Government hold a lien on the produce would always tend to lessen the breeder's interest in his young stud, because this lien would not mean that Government would take the animal from him on its arriving at a certain age, but that, provided it was pronounced by a Government Committee as up to a certain standard, Government would purchase it, and failing that, it would be thrown on the breeder's hand as a "rejection," thus damaging its reputation for sale in the open market. The standard fixed by Government is a purely arbitrary one, and of course has special reference to their own requirements; consequently the rejection by the remount committee may not disqualify the "rejection" from taking a good place as a generally useful animal. The term "rejection," however, so generally lowers its value, that the lien held by Government really acts as a wet blanket on the praiseworthy efforts of breeders.

THE report of the Saidapet Farm for the year ending 31st March 1879 has just come to hand. It contains the record of not a few interesting experiments which would have merited a few remarks and a considerable amount of general attention had they been told us nearly a year ago. These reports are needlessly bulky, and what is here told us in 134 foolscap pages might have been condensed into six, and placed before the public twelve months ago. We had intended noticing a few of the experiments tried, but as most of them have been referred to in various forms during the last twelve months, it would be a waste of time to notice them now.

THE report on cotton cultivation in the Punjab for the year 1878-79 tells of a somewhat improving state of affairs. We may here ask why such an important document has not seen the light till fourteen months after due date? These reports, to have any value, ought to be issued with the least possible delay. The cultivation of this staple has been making progress in the Punjab, the acreage under crop having been

1874-75	...	711,312	acres.
1875-76	„	698,393	„
1876-77	„	686,716	„
1877-78	„	679,836	„
1878-79	„	803,480	„

The out-turn of the preceding year was abnormally low, and was so on account of scanty rain. We find the average outturn of cleaned cotton in 1877-78 to have been 58lb., while in the year under notice it rose to 81lbs. This although a great improvement, is still only a fourth of what it ought to be, and what it might easily be if the cultivators were able to manure and irrigate their land. We find that 41 per cent. of the land was manured, although we have no doubt the manuring was of the very lightest kind, and that 58 per cent. was irrigated. The use of manure is gradually extending, and we find from the trade return of India, that constantly increasing quantities of oil-cakes are being retained in the country to be used either as manure directly or as cattle food. In either case the land must get the benefit of it ultimately, and while this increase in manure is apparent, we should like to see greater facilities afforded for irrigation, it being found that wherever a good rainfall is supplemented by irrigation, the outturn of cotton can be depended upon. Thus in Montgomery where we find 91 per cent. of the crop irrigated, we have an outturn of 217lb. per acre, and the estimated value of the crop is fixed at Rs. 36. This is the nett value of the outturn. At this rate cotton would pay the cultivator. On the other hand at Hoshiarpore, where only four per cent. is irrigated, we find the outturn 46lb. per acre, and the estimated nett value of the crop fixed at Rs. 10. Perhaps when we get rid of our craze about "scientific frontiers" and "gates of India," we may find a little money to bring water to those needy cultivators to

prevent them from falling a prey to absolute starvation. The percentage of irrigated lands was of course less than in the preceding year, because while the land under crop increased immensely, the quantity of water available is ordinarily a fixed factor in the calculation. In the Hoshiarpore district we find that the hand-looms manufactured cotton cloth to the value of 5¼ lakhs of rupees from English twist, and it is a little surprising that the enterprising natives of that rising province, the Punjab, do not engage in the cotton manufacturing industry. In the Punjab many advantages exist. There is a reasonably cheap labour supply, cotton is plentiful, and there exists a good market for all that could be turned out.

MORE than a year ago a movement was made for the establishment of a company, having for its object, "to trade in rice, paddy, cotton goods, &c., between Colombo and India on the one side, and Jaffna on the other." The scheme met with favour, and several reliable men signified their wish to become shareholders. For several months little was heard of the enterprise, and some fear has been expressed of a failure. It appears, however, that the movers have had no idea of relinquishing it, but have been, in a quiet way, taking the necessary steps to secure incorporation. To this end, an application was sent, in August last, to the Government; and on February 23rd of this year the company was duly registered. So far as its recognition by Government as a regularly organized company is concerned, it may be regarded as established and ready to carry out its object. The nominal capital of the company is Rs. 20,000 divided into 200 shares of Rs. 100 each with power to increase the capital.

NEW rules for cultivation leases of small lots of waste land in the regulation district of Chittagong are published in a recent *Calcutta Gazette*. It appears that the lands are to be used only "for the purposes of ordinary native cultivation," are to be granted in lots of about fifty acres, and the leases to be disposed of by public auction to the highest bidder. The first lease is to run in every case to the general year of resettlement for the district, *viz.*, 1898 A.D., and the lessees will have a right of resettlement on such terms and for such period as may then be fixed, provided that the resettlement shall not be for a less period than 20 years.

NOTWITHSTANDING the nature of the rules under the Burmah Land Revenue Act, it is pleasing to note the rapid extension of rice cultivation in the province, some 200,000 acres having recently been added to the area under it. The splendid alluvial fields of the province should make it the granary of the East, and as over twenty kinds of paddy are raised by cultivators, there cannot be much difficulty in suiting the most fastidious market.

IT is estimated that 818,500 acres have been added to the cultivated area of the Punjab during the last five years. Considering increase of population, and other conditions, this enlargement in the area seems fairly satisfactory. Nearly 3,664,000 acres, formerly classed as uncultivable, are now entered as cultivable.

OFFICIAL PAPER.

CANE BORERS.

1. *Mauritius.*—In 1856, the cane crops there were ravaged by a borer which was believed to have been introduced into the island with a cargo of cane cuttings brought from Ceylon. This borer was identified as the larva of a moth *Proceras sacchariphagus*. The moth lays its eggs on healthy canes in the axils of the leaves. The young caterpillars soon eat the leaves "from the tender parts of the heart of the plant, destroying the cane in a frightful manner, by forming burrows in the stem filled with excrement, and which shortly have the effect of completely disorganising the functions of the vessels; so that crystallisation will no longer take place, and the cane is not even fit for the making of rum." Such is Professor Westwood's description of the ravages of this insect (*Gardener's Chronicle*, July 1856), and he suggests with the view of getting rid of the pest "the burning of infested canes, as well as every particle of the tops, leaves, and dry straw which have fallen on the ground, and do not pass through the mill." As a precaution the Mauritius planters at this time immersed the cuttings of cane tops about to be planted in a solution of "pentasulphide of calcium" in water, consisting of one part of the former to thirty of the latter. Professor Westwood finally states that the Mauritius borer is identical with that described by the Rev. L. Guilding, in the Transactions of the Society of Arts XLVI., 143, under the name of *Diatræa sacchari*, and that this is the same as the *Phalæna saccharalis* of Fabricius.

2. *West Indies.*—In paragraph 6 of my letter, recorded in G.O. No. 22 of 6th January 1880, I promised to apply to the Entomological Society of London for a copy or abstract of Mr. Guilding's prize essay on the cane borers of the West Indian plantations, and have now to report that Mr. Distant, one of the Secretaries of the Entomological Society, has been good enough to send me an abstract of the paper. From this it appears that the chief enemies of the cane in the West Indies are as follows :—

Beetles	1	Calandra palmarum,	*Fab. Lam.*
		Curculio „	*Lin.*
	2	Calandra sacchari,	*Guild.*
Moth	...	Diatræa. „	

The following is the information abstracted by Mr. Distant from Mr. Guilding's essay as to the habits, ravages, &c., of the respective insects :—

"The Calandra palmarum is principally injurious to the plants lately stuck in the ground, to which the female is allured by the juices which are exuded. They do not seem to deposit their eggs in full-grown canes, when palms are abundant in the neighbourhood.

"Calandra sacchari confines itself principally to such canes as have been slightly injured, though it sometimes attacks the more vigorous plants, which it excavates to the very ground voiding its excrements in scarcely discolored grains, which fill up the passage.

"As regards the most destructive enemy, the grub of the moth which is most formidable in dry seasons, Mr. Guilding states, 'the object of the planters should be to prevent the insect from depositing eggs in the plants, rather than to kill those which have already begun their operations.'

'From long-continued experiments I have at last discovered that they may be almost entirely expelled from any quarter in which the canes are carefully stripped of the dry and useless leaves under which, as they become loose, the female borer deposits her eggs.

'The borers are observed to be much more fatal to planted than to ratoon canes, which should of course be often visited by the parties of negroes whose business it is to collect the trash.

'The myriads of ants which once infested, but have now disappeared from Grenada, committed indeed the most frightful ravages, but it was rather by excavating their little metropolis beneath the roots than by attacking the body of the cane. Were there little carnivorous agents less prolific than they are, we might encourage them as useful helpmates in the destruction of the borers, which they pursue and kill in their cylindrical labyrinths.

3. *British Guiana.*—At the present time the "sugarcane borers" are doing much harm to the crops in this colony, and the enemies are apparently the same as those described in Guilding's essay. The moth is a Proceras and "causes injury by attacking the young canes, and the treatment applied is to cut back the cane below the surface of the ground, covering the plant with mould, and adding a handful of lime. (Trans. Entomolog. Society, p. XXXIV., 1879). The larva of this moth penetrates into the heart of the cane where it drives galleries fifteen, eighteen or more inches in length. The injury done by this pest, however, "is said by one of the chief planters in the Demerara district to be as nothing compared with the effects of the *Calandra sacchari*, the orange-brown weevil." The larva of this beetle is stated to riddle the heart of the matured canes to an incredible extent, leaving only the outside rind, without killing the leaves at the head of the cane, so that in cutting away, suspected plants may escape notice. On opening a fair-looking cane the contents are found to be a mass of decayed and decaying matter, the greater part having been converted into excreta resembling sawdust. The injury inflicted is twofold, as not only are many canes lost, but others containing insects escape notice and pass through the mill, the result being a discolored, sticky, and disagreeably smelling syrup. The third enemy, *Calandra Palmarum*, is much less destructive than the other two, and is believed to follow them and finally destroy bored canes. Long droughts and hot weather, preceded the invasion of the borer pest in Guiana and are said to have, in great part, driven from the fields the colonies of ants which are the natural enemies of the borers, keeping them in check by eating their eggs and larvæ. As remedies it has been proposed to steep the cane cuttings in water for forty-eight hours, or for ten or twelve hours in a mixture of 1lb. of carbolic acid to 100 gallons of water. The encouragement of ants is also inculcated, and the value of their presence is illustrated by the following extract from p. XXXIX., Trans. Entomolog. Society, 1879:—

"On week ending the 3rd of May, a twenty-acre field of canes was set fire to and cut down, after all the canes had been sent to mill; the rubbish from the field was also thoroughly cleared. Two twenty acre fields adjoining were also in turn, burnt and cut down; and two other fields near were next reaped after the canes had been ground. On the three fields which were burnt on the ground, the spring of canes in the first was weak and unhealthy, ants few, and canes attacked by Proceras; on the second and third, the spring was good, but ants similarly not numerous and canes attacked by Proceras; whilst the fourth and fifth fields in which the cane was reaped threw up healthy shoots, "an army of ants"

appeared on every bed, and there were no signs of any stool having been attacked by any of the borers.

"The writer from this draws a very correct conclusion :—

"It is evident that to burn fields in which the small red or black ants are to be found in abundance, is a mistake, as large numbers of the best friends of the canes must inevitably be destroyed by the fire. To entice ants and other insects known to be antagonistic to grub-life, is of vital importance, and no trouble should be spared in getting them into the cane-fields."

"From these notes it appears to me that a process of certain destruction to the natural enemies of the borers has, in some cases, been going on, by which the ants and their nests are swept off the fields together. In cultivation spreading over great areas, as in sugarcane culture, it is the natural balance that must chiefly be looked to for protection. Clearing off infested canes by every available means is most important, whether by cutting off, grubbing up, or any other means, and utterly destroying these infested pieces, including amongst them rotten cane thrown aside, which is notably attractive to Calandra. But though no way is so thorough as destruction by fire for the perfect clearance of these infested canes, they should not on any account whatever, be burnt on the surface of the fields. A few straggling ants burnt on the heaps, are of no account, but if the remains of the standing crop are burnt in the fields, so as to spread the fire over the surface, or in any other situation whatever, where the fire can destroy the ants' nests, it is a loss by each nest destroyed of so much skilled protection to the cane crop."

4. The chief remedies proposed for cane borers are therefore as follows :—

(a) To steep the cuttings in water for forty-eight hours so as to destroy the grubs.

(b) To steep the cuttings in a watery solution of some chemical, such as carbolic acid destructive to insect life.

(c) The removal of dry and useless leaves, the cutting out of all infested canes, and the burning of all these away from the cane fields.

(d) The encouragement of ants in the cane fields, they being the natural enemies of the borers.

Mr. Distant in his letter already referred to says:—" We have lately had several communications respecting the ravages of the cane borers in the West Indies, and I myself have had personal experience of the same when in province. Wellesley, Straits Settlements, some few years since. The best remedy, I believe, and the most efficacious one, is searching for the infested canes and *burning* the same." This is practically the same as the recommendation made by myself in my letter in G. O. No. 22, of 6th January 1880.

SELECTIONS.

THE INFLUENCE OF CLIMATE ON AGRICULTURAL CROPS.

DR. J. B. LAWES of Rothamsted favours us with the following interesting article :—

I have been quite lately occupied in writing a paper on the influence of the season of 1879 on the wheat crops at Rothamsted, in which I attributed much injury to the washing out of the nitric acid. I had just forwarded this paper for publication when I received an urgent summons to Scotland to record a vote at the present election.

In the course of my hurried journey to Argyllshire, my mind was directed towards the distinction between the system of agriculture, as practised there and at Rothamsted; and I asked myself how it was that, while the crops at Rothamsted were almost destroyed by an increase in the rainfall of from 26 to about 40 inches in the year, the agriculture of Argyllshire is carried on under an ordinary rainfall of about 80 inches, which in wet seasons may be increased to 100 inches.

If 40 inches of rain washes so much nitric acid out of the soil, what can be left in it when the rainfall is double that amount ? and can the plants in the two localities feed upon different compounds of nitrogen ?

The subject is one of considerable interest to those who possess Highland property, and more especially those who advocate an extensive conversion of pasture into arable cultivation. I have only twice visited Argyllshire in the spring, and on both occasions have observed that, in perennial vegetation, it was quite as forward as Rothamsted ; the larch was perhaps rather more forward at Dalmally, and the same spring flowers were in full bloom in both places.

With the summer and autumn climate I am tolerably familiar. Independently of the great rainfall, the air is essentially moist ; the temperature is never high in summer, but the nights are not cold; the winters are mild, and I should say that pasture grasses would grow, either above or below ground, over a much larger portion of the year in Argyllshire than at Rothamsted.

Compared with Argyllshire, the summers at Rothamsted are hot, and the air is dry. Our three principal crops—wheat, barley, and mangels—thrive in a dry soil and a dry atmosphere, and therefore could not be cultivated with any great success in Argyllshire.

At Rothamsted, our chief endeavour is to keep the land as free as we can from vegetation of any sort except that of the growing crop ; the result of this is that the land is practically bare of vegetation during the greater portion of the year. It is only when we take a clover crop, which may be once in from six to eight years, that the land is covered with vegetation during the whole twelve months.

At Dalmally, the land under the plough is cultivated as follows :—Potatoes with dung, followed by oats with seeds. Some years ago the large sheep farmers used to keep the land in grass for two or three years before it was broken up again ; but, within my memory, arable cultivation, as far as they are concerned, has almost died out, and at the present time it is confined to the crofters, who break up the land after it has been in grass one year.

Before I attempt to show why the increase in the rainfail at Rothamsted has been attended with such injurious effects, due probably to the washing of nitric acid from the soil. I must first make a few observations with regard to the compounds of nitrogen generally ; and further, must beg your readers not to accept my views as being established facts, but rather as an attempt to explain much which is still very obscure.

In all soils the great bulk of the nitrogen is found in combination with carbon, in a very insoluble form. When produced by the decay of an aquatic vegetation, it assumes the form of peat: while in ordinary soil the decay of land vegetation takes the form of humus. Here I may mention that, in the Highlands, the colour of the rivers is due to minute quantities of dissolved peat.

It is rather remarkable that Dr. Frankland, whose investigations, undertaken on behalf of sanitary purposes, are quite as valuable to agricultural science, found no nitric acid in the rivers which take their origin in the mountain ranges of Scotland. The Dee, the Don, the waters of Loch Lomond and and Loch Katrine, contain no nitric acid ; while the water percolating through cultivated soils contain it in abundance.

Dr. Frankland, I believe, considers that this formation of nitric acid has its origin in previous animal manures. The recent discoveries of Schlœsing establishing the fact that the conversion of ammonia into nitric acid is due to a minute plant would rather lead me to attribute to this plant functions somewhat similar to those of the yeast plant, which requires for its support alcalis and phosphates just as much as the crops we grow.

I should expect to find that lime, kainit salts, and phosphate, applied to a peaty soil, would produce a luxuriant vegetation, and that the water passing through it would contain nitric acid.

In any case I think, however, that whatever may be the operating causes, it may be accepted as a fact that nitric acid is constantly being generated in all cultivated soils, and that it is greedily taken up by vegetation with more or less rapidity, accordingly as the condition of temperature and moisture is favourable ; while any residue not so taken up is washed out of the soil.

Nitric acid, when once taken up by plants, becomes insoluble ; but a portion may soon again become the food of plants, as when succulent vegetation is ploughed underground ; while another portion may not again become soluble for years, or even centuries, as is the case when woody matter is buried in a stiff soil

Even weeds, inasmuch that they arrest soluble nitric acid, perform an important function in the economy of growth ; and thus the remarkable effort which Nature puts forth to clothe every bare spot upon the earth with vegetation receives its true explanation.

Quite independently of, and in addition to, any nitrogen received from the atmosphere in the rainfall or by condensation, we have a continuous formation of nitric acid, derived partly from the stores of nitrogen due to a vegetation, the origin of which must be extremely remote, and partly due to nitrogen supplied in manure.

The power of taking up nitric acid depends upon the plant being able to obtain the necessary mineral food. This being present, as the period of active vegetation in a corn crop is confined to a small portion of the year, it is obvious that much more nitric acid would be required in the soil for its support than in the case of a perennial crop ; as also that, under unfavourable circumstances, much more loss would be incurred by washing away—in fact it would almost appear as if the successful cultivation of corn was dependant upon an amount of rain which did not in summer wash nitric acid from the soil.

Having made the above preliminary observations, I will now go on to compare the arable cultivation as it exists at Rothamsted and in Argyllshire.

I have said that wheat, barley, and mangels are the principal crops grown at Rothamsted ; but in order to obtain a produce of from four to five quarters of wheat, or from five to six quarters of barley, it is absolutely essential that the soluble nitrogen in the soil should far exceed the amount we find in the crop. If from any cause the wheat or barley is unable to take up this soluble nitrogen, it is altogether lost, as there is no vegetation to fix it after the crop is once ripe.

Mangels have a longer period of active growth, and do in fact assimilate a larger amount of a given supply of nitric acid than the corn crops ; still the land under mangels is frequently without vegetation until the following spring. It will be seen, therefore, that this course of cropping is dependant for its success upon a comparatively small rainfall.

If an increase in rainfall, such as we have had in recent years, were to become permanent, a different system of agriculture would of necessity have to be pursued.

At Dalmally the potatoes receive the dung which lies outside the cottages, exposed to incessant rain. It may be rich in minerals, and may yield a

certain amount of soluble nitrogen by decomposition in the soil, but the chief source of the nitrogen gathered by the crop must be that already existing in the soil. The potatoes spread an immense network of roots through the porous soil of the district, and thus further arrest the continuously forming nitric acid before it can be washed away.

As seeds are sown with the oats, the land is never free from vegetation, except between the periods of raising the potatoes and of sowing the oats.

If we compare two periods of three years' crops at Rothamsted and Dalmally, it may be said that at the former place no vegetation of any sort exists during eighteen months of the three years; while at the latter there are only six months of the whole period which are free from vegetation.

But even with this rotation, so well adapted to the climate, I am yet disposed to think that if all the arable land at Dalmally were in the hands of one tenant-farmer, and cultivated by paid labour, there would be no surplus to pay rent or interest upon capital.

This, however, is quite a separate question, and the importance of perennial vegetation, in a climate where the rainfall is heavy and the temperature sufficiently high to permit of growth either by leaves or roots during a great part of the year, is clearly indicated.

A few years ago the Duke of Sutherland was kind enough to show me the magnificent operations for clearing land and preparing it for the plough, in which he was engaged on his Highland property.

I was disposed at the time to think that his labours would have been better directed towards the improvement of the pasture than its conversion into arable land; and at that time I did not know so well as I do now the great losses which occur upon arable land in a wet climate.

It is true that on the east coast of Scotland the rainfall is less than it is on the west; still, even a rainfall of from 40 to 50 inches per annum, combined with a moist atmosphere and a low summer temperature, does not furnish a climate suited for arable culture. I am therefore more than ever disposed to think that any extensive improvement in the Highlands must take the form of perennial vegetation.

The adaptation of climate to the system of cultivation and the crops to be grown has not received the attention it deserves.

Before concluding, there is one other point in connection with this subject on which it may be well incidentally to add a few words. I allude to peasant proprietorship. While many may wish to see a larger portion of the soil of Great Britain in the hands of peasant proprietors, and the habits of prudence and economy which such an ownership would enforce more widely extended, they ought not to be misled by the writers on political economy, who draw no distinction between the climate of Great Britain and that of other countries where cultivation by peasant proprietors largely prevails.

A system of cultivation which might be carried on successfully in France or the Island of Jersey, might be rendered simply impossible by the climate in less favoured localities.

Climate, then, is an important factor in all operations connected with the production of crops; though to what extent the climate of the British Isles is responsible for the accumulation of the land into the hands of so small a proportion of the population is a question on which I am not at present prepared to enter.—*North British Agriculturist.*

RICE CULTIVATION IN BURMAH

IN the Revenue Administration Report for 1878-79, the cultivation of rice, the staple produce of this province, is prominently noticed. The cultivation of rice, of late years, especially since the Bengal famine period, has received considerable impetus. Year by year large areas of land are being taken up for this purpose, cultivators being to a large extent encouraged by the abnormal prices which they obtained during the prevalence of scarcity in both Bengal and Southern India, to say nothing of the drain on our grain sources from the Upper Burmah side. The consequences of a steady foreign demand was to convert abnormal values into ordinary ones; and many a miller must, we imagine, sigh for the pre-famine times when the season used to open at Rs. 50 or 55 per hundred baskets of paddy. But there can be no doubt that, if present prices of paddy are not altogether attributable to the operations of speculators, the latter have at any rate helped to maintain them, seemingly not with altogether satisfactory results, since a re-action has of late been perceptible, which is indicative of a fall in prices for the future. Before pursuing this subject, it may be as well to give a few figures showing the position of this commodity during the year under review. The total area of land under paddy cultivation was 2,728,448 acres, which compared with 2,554,853 acres, in the previous year, shows an increase of 173,595 acres, or close on 7 per cent. The assessment for 1878-79, was Rs. 45,23,460 against Rs. 42,32,745, showing an increase of assessment of Rs. 2,90,715. Of this increase in cultivation Pegu claims 136,376, Tenasserim 24,005, and Arakan 18,214 acres. The gain to revenue has not been quite in keeping with the increase of cultivation, as new lands taken up are often exempt from taxation for several years.

In Pegu the enormous increase of rice cultivation, as compared with that noticeable in the other divisions, is no doubt "greatly due to the active demand and high prices prevailing for paddy, which induced many to abandon their old employments and take to agriculture as being more profitable." The Report, however, leaves out of account the great encouragement to cultivation by the increased facilities of carriage afforded by the construction of the Rangoon and Irrawaddy State Railway, without which the high prices prevailing could not be availed of in many districts.

There has been a tendency of late years on the part of Government to increase its imperial revenue by a higher assessment of the lands under cultivation. Although we do not say that this is not justified by the profits made by cultivators, yet considering the large tracts of land still uncultivated, it is a moot point whether for the present it would not be better to increase the revenue by encouraging an increase of cultivation, than by the enhancement of the land tax upon the area already under cultivation. However, much practice under modifying circumstances may be opposed to theory, it is incontrovertible that in principle the direct tendency of increased taxation is to discourage an increase of any industry on which such taxation bears. What is first imposed on the agriculturist will, we may be certain, have to be ultimately borne by the merchant and the consumer, whereas every encouragement we can give for an increase of cultivation improves the revenue at the same time that it helps to increase the population—a great desideratum in this country—and keep down prices of the produce, to the cheapness of which as compared with that of other countries so much of the prosperity of the province is due. We need not grudge the Burman cultivator the extra profit he may make in abnormal years, because it all comes back to Government in another form. The Burman seldom or never hoards his gains; he spends freely in silks and other European wares his profits, and on all these Government imposes a duty heavy enough to represent almost as much as the enhanced taxes would amount to. Besides, the Burman cultivator's gains are not so great as they may seem. In a great many cases the cultivator carries on his operations on borrowed capital, paying not unfrequently as much as 3 per cent per mensem for the accommodation, so that he has need to make a fair profit in order to stand such usurious interest, as well as to make a living and meet the Government demands, to say nothing of the losses he has to bear in the deaths of cattle and other causes. We know that in the year under review, when the rinderpest was prevailing, about 50,000 cattle must have died. It is something to be able to point to our cultivators, as being conspicuous for the absence of defaulters among them in the matter of the land tax. Our revenue is yearly and steadily increasing by something over ten per cent. Let us be satisfied to see the people happy, rich, and contended, trade and commerce flourishing, and our harbours full of shipping, which come to us because they can get our grain cheaper here than anywhere else, and because the people are rich enough to buy largely of the goods they bring instead of their being rackrented and needy, like the ryots in many parts of India, who are over head and ears in debt, from which nothing but death will ever release them.

Let us see what, according to the date furnished by the Report, the profits of a cultivator are—say in the Prome district, where seven different rates are said to prevail—for 10 acres, at a minimum yield of 25 baskets an acre (the maximum being 50 baskets). At the minimum price of Rs. 53 which ruled in 1872, 10 acres would be valued at Rs. 132-8-9, and the cost of cultivation as follows:—

	Rs.	A.	P.
One pair of buffaloes	15	0	0
Sowing, 25 men, for one day	12	0	0
Reaping ditto	12	0	0
Seedlings	10	0	0
Land-tax	15	0	0
Total ...	65	0	0
From value of gross produce	132	8	0
Deduct actual expenses	65	0	0
Minimum profits ...	67	8	0
Therefore for one acre the minimum profits in decimals would be	6·78		

The maximum profits would of course be just double this (Rs. 13·56) in the year 1872-73.

The highest market rate of paddy is shown to have been attained in 1877-78, viz., Rs. 109 the hundred baskets.

Assuming the yield to have remained the same, as stated in the above computations, the maximum profits for 1877-78 were Rs. 37, and the minimum profits Rs. 20 38 per acre.

In 1878-79 the price being Rs. 90, the maximum profits were Rs. 35 70, and the minimum profits Rs. 17·85.

These figures do not, however, allow for loss of cattle or interest at 3 per cent per mensem for six or eight months, or the loss by floods, which, although they may bring the cultivator a remission of the rent, will not perhaps recoup him for the outlay he has been put to, or the interest and principal due to the money lender. Even supposing all this were allowed, taking one year with another, and admitting the profits on one year on 10 acres to be Rs. 135, instead of Rs. 67, as in the foregoing calculation, surely a net profit of Rs. 13.8 per acre for a year is not so great as to warrant an enhancement of the rent. A family holding 100 acres would thus have left them Rs. 1,350 for a whole year's labour, on which to live, renew stock, &c. Sometimes in order to get advances a cultivator has to

mortgage his lands and cattle, and give an undertaking to deliver paddy at a low rate to the lender, all which naturally tends to lessen his profits a good deal beyond what the ruling rates would lead us to believe he really gets.—*Rangoon Gazette.*

ADULTERATED MANURES AND FEEDING STUFFS.

THE following report by Dr. Voelcker, submitted and approved at the Council meeting of the Royal English Agricultural Society the other week shows the vigorous action taken by the Society when their chemist detects adulteration in manures and feeding stuffs sold to members. It seems a pity that the name of the manufacturer of the Norwich manure was not submitted to the Society. The report which details the proceedings of the Chemical Committee for the quarter is as follows:—

1. A sample of nitrate of soda was sent on June 9, 1879, by Mr R. B. Stafford of Bedford, which he had purchased of Mr J. Brightman, Lower Staughton, St Neots, who informed Mr Stafford that he obtained the nitrate from Messrs. H[illegible] & Co. of Colchester House, A[illegible]

On analysis this nitrate [illegible] the following results:—

Moisture	3·65
Chloride of [illegible]	56·50
Other impurities	1·50
Pure nitrate of soda	38·35
	100·00

The nitrate was bought [illegible] per ton, and according to the purchaser's statement, was verbally guaranteed to contain 92 per cent. of pure nitrate. It will be seen that the [illegible] sent by Mr. Stafford was adulterated with more than half its weight of common salt, and according to the price [illegible] it was worth only £5.8.6 per ton.

Reports of previous cases of samples [illegible] stated to have been supplied by Messrs. Hale & Co. have already appeared in the quarterly reports of the committee. To these it will be seen that Messrs. Hale & Co. repudiate all responsibility for anything done or said by or to their agents, never sell by analysis, and treat Dr. Voelcker's remarks with derision.

2. Another sample of nitrate of soda was sent on 8th July by Mr. Geo. Church of Bedford, who purchased it from the same vendor, namely, Mr J. Brightman, of Lower Staughton, St. Neots, the price paid being £14 per ton, with a verbal guarantee of 95 per cent. of pure nitrate. This sample on analysis gave the following results:—

Moisture	[illegible]
Chloride of sodium (common salt)	41·59
Other impurities	[illegible]
Pure nitrate of soda	[illegible]
	100·00

In reply to the usual inquiries and request [illegible] Mr. Church stated that 'there being a [illegible] credited my account with the [illegible] according to this analysis, and the price [illegible] the sample sent by Mr. Church [illegible]

3. On the 20th of August 1879, a sample of [illegible] Mr. F. Monckton, The Cage Farm, Tonbridge, [illegible] received it direct from London. This sample yielded on [illegible] the following results:—

Moisture	[illegible]
Chloride of sodium	[illegible]
Other impurities	[illegible]
Pure nitrate of soda	[illegible]
	100·00

According to the statement of the purchaser, this nitrate was bought with a guarantee of 95 per cent. pure nitrate at £14-15 per ton, delivered at Tonbridge, [illegible] most respectable firm in this neighbourhood, but received direct from London by South-Eastern Railway from the importers.

Mr. Monckton subsequently wrote —

'I have had transactions for years with the firm for cake, &c., and *particularly* wish their name kept from publication. It was at their suggestion I sent the soda to Dr. Voelcker; it was guaranteed 95 pure to them. I may add, I think it was a positive injury, as I applied the lot in question to stimulate hops, but having so much salt in it, and the weather following the application being wet and cold, the hops I believe would have been much better without it.'

The purchaser having complained to his vendors, received the following letter from the importers :—

'DEAR SIR,—We understand from Messrs.—— that you were the receiver of 1 ton nitrate of soda forwarded by us to Tonbridge station on their account on the 16th August last; also that you have had this nitrate analyzed by Dr. Voelcker, whose analysis shows a refraction of nearly 25 per cent. The writer of this was from home when the complaint reached us, but upon his return we wrote Messrs.—— fully upon the subject, and at their request we can only repeat to you the substance of our communication to them. We never in our experience knew of nitrate of soda *as imported* showing a refraction of anything like 25 per cent. This, coupled with the fact that the test of Messrs. Huson Bros., analysts for the cargo, only shows a refraction of 5·50, induces us to believe, either that some mistake has taken place in your sampling or in Dr. Voelcker's analysis.

'The nitrate which you received was delivered by the St. Katherine's Dock Company *from ship's side* to a public carman's vans, by which it was conveyed to the railway station. All this we can incontestably prove, and we are perfectly satisfied that nothing but nitrate *as imported* was sent to you.

'As mentioned to Mr.——, we are willing to go personally and see the article complained of, and sample it in conjunction with you; and if it is still in your possession, we leave you to fix a day for this purpose.

'We addressed a letter to Dr. Voelcker yesterday in regard to his analysis, informing him of the result of Huson Bros.' test, and asking him to look over his analysis.

'We enclose his reply, from which you will observe that he makes it a rule to correspond only with the *sender* of the sample. Kindly return his letter to us. * * *

In answer to further inquiries, Dr. Voelcker received the following letter from Mr. Monckton :—

'The Cage, Tonbridge, Sept. 20, 1879.

'DEAR SIR,—I should have written before, but was anxious to afford you as much information as I could. The sample I sent you was taken from two bags only, as the rest were in the field, and nearly all used. I have portions of two bags that were left after the men had finished sowing, and from which Mr.—— of the importer's firm, who came to my farm on Tuesday last, carried away samples to be analyzed. I enclose the analysis, which I received this morning, and at the same time an account from the firm I ordered the soda from, deducting 19s. 9d. from the amount first charged, £16-11-9 for 1 ton 1 cwt. 7 lb.—Yours obediently,

'Dr. A. Voelcker. FRED. MONCKTON.

CERTIFICATE OF REFRACTION.

'London Commercial Sale-rooms, Mincing-lane, E.C., and No. 1, Highbury Park, North, N.

Original, London, Sept. 17, 1879.

'We hereby certify that we have examined the refraction of the undermentioned nitrate of soda, and that the following is the result, viz. —

'Per "Tonbridge." 12 lb per cwt. refraction.

E. F. TESCHEMACHER AND J. DENHAM SMITH,

Insoluble and moisture	4·25
Sulphates	·10
Muriates	7·65
	12·00

'Sample received, 16-9-79.'

This case is not without difficulty, and shows that some tampering with the cargo must have taken place, but the committee are unable to trace when this was done, and they publish the case to show that it is safer to buy by guarantee, and have all samples analyzed.

4. Mr. [illegible] Wallis, Home Farm, Dillington, Bradenham, Norfolk, steward to W. A. T. Amherst, Esq., wrote on date the 25th as follows :—

'DEAR SIR,—I have a lot of manure, I should like to have a sample of analyzed on behalf of W. A. T. Amherst, Esq., Dillington Hall (a member of the R.A.S.E.). May I request you to write me what your charges will be, and whether I may send it or not. It is sold at £5 per ton, as a mixture of rape cake, blood, and bones, for turnips. Will you give me an idea as to its value.

The following is the analysis of this substance :—

Moisture	27·08
Organic matter	20·32
Phosphate of lime	2·49
Oxide of iron and alumina	1·50
Carbonate of lime, &c.	15·58
Alkaline salts	1·72
Insoluble siliceous matter	31·31
	100·00
Nitrogen	·74
Equal to ammonia	·89

In sending this analysis to Mr. Wallis, Dr. Voelcker stated that he would think twice about it before he decided to buy such stuff, if it were offered to him at £1-1 a ton.

The following communication was received from Mr. Wallis in answer to the usual inquiries —

'DEAR SIR,—I thank you very much for analysis received. I am sorry to say it is pretty much as I expected. I had hoped it would turn out better. I only purchased a small quantity from the maker. I have written him, enclosing copy of your analysis, and stating that I do not intend paying more than your valuation unless compelled, and claiming damages; I will let you know the result. I am not the only one bitten.'

Subsequently Mr Wallis wrote as follows :—

'DEAR SIR,—The maker has receipted his bill for the manure you analyzed for me, without payment. I had some trouble with him.'

The maker's name is not published, simply because Mr. Wallis threatened to have it published unless the bill was receipted without payment. It was a Norwich production.

5. A sample of bone dust, bought as pure ground bones, at £8 a ton, was sent by Mr. George Rodger, Arden House, Altrincham. On analysis it yielded the following results :—

Moisture	22·45
*Organic matter	13·98
Phosphate of lime	13·75
Caustic lime	3·35
Carbonate of lime, &c.	27·11
Insoluble siliceous matter (sand and earth) ...	19·36
	100·00
*Containing nitrogen	1·02
Equal to ammonia	1·24

This sample, it will be seen, was very damp, and much adulterated with lime-rubbish, or mortar, sand, and brick-dust; and in comparison with pure bone-dust selling at £8 a ton, was scarcely worth £2 a ton. No particulars as regards the vendors could be obtained.

6. A sample of artificial manure, sent on May 13 by Mr. James Thompson of Anlaby, Hull, was bought at £6-2-6 on the following analysis :—

ANALYSIS OF MANURE ORDERED.

Moisture	11·3
*Organic matter and water of combin	21·1
Monocalcic phosphates	9·5
Equal to bone earth made soluble (15 per cent.),	
Nitrate of soda and potash	15·5
Insoluble phosphates	4·2
Sulphates of potash and magnesia	10·4
Sulphate of lime	24·0
Insoluble matter	3·0
	100·0

*Containing nitrogen equal to 6·8 per cent. sulphate of ammonia.

An examination of the sample sent yielded the following results :—

ANALYSIS OF MANURE RECEIVED.

Moisture	16·38
*Organic matter and water of combin	25·60
Monobasic phosphate of lime	7·12
Equal to tribasic phosphate of lime (bone phosphates) rendered soluble	(11·15)
Insoluble phosphates	9·78
Sulphate of lime, alkaline salts and magnesia	26·45
Insoluble siliceous matter	14·67
	100·00
*Containing nitrogen	2·05
Equal to ammonia	2·49

An examination of the preceding analysis will show that £6-2-6 is as fair price for a manure having the composition indicated in the analysis upon which the manure was purchased, while the sample analyzed by Dr. Voelcker was not worth so much by at least £1.15 per ton. In answer to inquiries, Mr. Thompson stated that his order of 8 tons of this manure was executed on May 9th in Hull.

Mr. Thompson subsequently wrote to the Secretary as follows :—

Anlaby, 7th January 1880.

'DEAR SIR,—In answer to your letter of January 5th, I beg to inform you that the correspondence was given up at the time the account was paid. With regard to the payment, the price I paid for the manure was the price Dr. Voelcker stated it to be worth. I may say that when the matter came to be looked into, it was found that a wrong manure was sent to me from the works by mistake ; and although Mr.——personally superintended the putting up of my lot, yet he did not superintend the delivery of it. When the mistake was found out, it was too lat to be remedied, as the greater part of the manure was then in the ground. This being so, it was agreed that I should pay the price put upon it by Dr. Voelcker, and so end the matter. As I believe this to have been purely a mistake, I must beg that if notice of this transaction appears in the *Journal* of the R.A.S.E., no names may be mentioned. In proof of it being my candid opinion that the manure sent to me was a mistake, I may say that it is my intention to purchase my turnip manure for this season from the same firm.—Yours faithfully,

JOS. THOMPSON.

'H. M. Jenkins, Esq.,

12, Hanover-square, London, W.'

7. The following case was referred to Dr. Voelcker by Mr. Sanday, of Wensely House, Bedale, Yorkshire :—

MILK SUBSTITUTE FOR REARING CALVES AND PIGS.

A cream-coloured meal, sold at 35s. per cwt., as a milk substitute for rearing calves and pigs, and described in the hand-bills as a preparation consisting of 'highly nutritious and flesh-forming substances,' and 'the most perfect soluble food in the world,' on analysis was found to have the following composition :—

Moisture	20·85
Oil	·40
*Albuminous compounds (flesh-forming matters) ...	2·87
Starch and digestible fibre	74·35
Woody fibre (cellulose)	1·03
Mineral matter (ash)	·50
	100·00
*Containing nitrogen	·46

The meal appeared to have been kept in a rather damp place, for it contained more moisture than ought to be present in meal. It consisted almost entirely of starch—probably potato-starch—coloured slightly yellowish. It was very poor in nitrogenous or flesh-forming matters in which milk abounds, and a most unsuitable substitute for milk in rearing calves and pigs.

The following is a copy of the hand-bill :—

MILK SUBSTITUTE
For Rearing Calves and Pigs,
Manufactured only by
SPOUNCER & SONS, GAINSBORO.'

'This preparation consists of highly nutritious and flesh-forming substances, and is the most perfect soluble food in the world.

'Almost every farmer admits that if his supply of milk were greater he would rear more calves and pigs, and thus increase the number of his stock.

'It is an acknowledged fact that if a calf be given new milk until it is a fortnight old, it can be well and profitably reared on milk substitute without the use of skimmed milk.

'As the substitute does not go sour and derange the stomach, the calf will not be so susceptible of scouring, but will, as a consequence, be more healthy.

'The following is selected from a number of similar testimonials :—

"'Grove Cottage, Lenton, Nottinghamshire,
August 7th, 1878.

"'I am so well satisfied with your Milk Substitute, I would be glad if you will forward to me one of your 35s. bags to Lenton Station. I shall be glad to recommend it to my friends, feeling persuaded it is a most useful and economical substitute for milk, and am only sorry I did not hear of it earlier."

'Directions for use.—One measure of the powder to be mixed with cold water to the consistency of cream, then add three quarts of boiling water stirring briskly all the time.

'Sold by agents throughout the Kingdom, in bags at 4s. 9d., 9s. 3d., and 18s. each, or 35s. per cwt.

'Agent—S. Parr, Pharmaceutical Chemist, Nottingham.'

Dr. Voelcker strongly urged all purchasers of artificial manures and feeding stuffs not to use those articles until they had received from him notice whether they are of equal value to the guarantee which the Chemical Committee had so frequently recommended should be obtained at the time of purchase. The committee had considered Dr. Voelcker's paper on the comparative value of soluble and insoluble phosphates, and they recommended that it be published in the next number of the *Journal*, and that certain experiments named at the conclusion of the paper be carried out at Woburn, with the view of arriving at some definite conclusion on the subject. The committee had received and approved of the report of the Woburn Sub-Committee.—*North British Agriculturist.*

INDIAN *versus* AMERICAN COTTON.

As far back as 1858 we remember to have seen in the hands of Mr. W. F. Stearns, the founder of the firm of Stearns, Hobart & Co., some small sample bales of Indian cotton placed side by side with similar fancy bales of American cotton. Mr. Stearns had a very good opinion in those days of Indian cotton, and much has been done since then to increase the beauty of its texture. Even then "Fair Dhollera" seemed to hold its own against Orleans Sea Island cotton, the chief difference being found to be in the length of the staple. Since then several Bombay firms have had representatives in the cotton-growing districts, and it was in one of these districts that the late Michael Scott showed that great ability which afterwards made him so necessary to his firm. At the time of the American war the high price realized for Indian cotton made it well worth the while of the large Bombay firms to maintain an agency in the cotton districts. Though cotton has declined in price, these agencies have been maintained and their number has been increased. Dr. Forbes Watson has now shown in a report on the quality and cleaning of Indian cotton, that it rests with the people of India to greatly increase the marketable value of this commodity. The natives are sharp enough to discover what is for their own interest, and though opposed to what they consider innovation in industry and agriculture, yet when they see that some new plan of improved cultivation is for their pecuniary interest they adopt it very readily. The reduced prices of cotton at the present time have been discouraging to the enterprise of cultivators, the Cotton Frauds Act also held them back from sending their cotton to market, partly because they are naturally timid, and partly because, with all the care of the European and superior officers of the department, the Act was used by some of the subordinates in a harsh

and arbitrary fashion. The success that has attended European agencies in many parts of the country ought to encourage the prosecution of this system for the improvement of the industry, especially now that the Cotton Frauds Act has been abolished, and the officers sent to other work. In regard to cotton, as well as to almost every industry which has been developed in India, there is no reason why it should not be able to compete with other countries and carry of the palm. Dr. Forbes Watson in this report makes a comparison between the length, strength, and thickness of the fibre of the American and the Indian cotton, and on this comparison he places India in a much higher position than is usually given to her in her competition with America in regard to this staple. In measuring three hundred specimens of American and Western and Southern India fibres, it was found that the comparative main length of the staple of American cotton was 1·02 inch to 1·04 inch, while the main length of Indian cotton was ·92 inch to ·93 inch; the average difference therefore amounted only to one-tenth of an inch, the relative proportion of the two, as regards amount of the longer staple is the reverse, the one of the other; of 199 American samples, and 68 Indian samples, of the American 78 per cent. were above one inch in length, 22 per cent. below an inch of the Indian, 72 per cent. were below one inch, and 28 per cent. above. Dr. Watson, therefore argues:—If the whole of the American and of the Indian samples were each divided into two equal groups, the inferior half of the Indian samples would be exactly matched as regards length by the superior half of the Indian samples, leaving only one half of the American samples as superior to the Indian cotton, and one half of the Indian samples as inferior to the shortest American cotton. We thus arrive at the important result that one-half of the whole bulk of American cotton imported into England could be matched as regards length of staple by cotton grown in India. "The investigation of the questions of strength and thickness are equally important. The average thickness of the American cotton is less than the Indian the former being one-thirteen hundredth of an inch, the latter one-twelve hundredth of an inch. The Indian cotton is in no respect inferior in strength to American cotton, the sample of cotton which contained the largest proportion of the strongest fibres was one from Coompta, its mean breaking weight was 163·7 against 83·9 for one kind of American Sea Island cotton. Indian cotton has a few minor disadvantages; but on the whole it stands a fair comparison with the best American cotton, and promises to reward any efforts made to improve it. Care in the production, care in the packing, cleaning, and ginning are required to place it on a par with the cotton sent to England from the United States. Dr. Forbes Watson expects that much improvement will result from the nearer approaches of Europeans to natives in the development of this industry. European energy will supplement the patient endurance of the native cultivator, and help him on the perseverance even in the face of obstacles. The only way in which Europeans can evince their gratitude to the great creator for the benefits bestowed upon them is—by making themselves useful to others, even to those who are unthankful for assistance and help rendered to them.

This country has large resources at its command which have never yet been developed: riches of agricultural, mineral, and industrial wealth which, if brought to the light, would make us cease to fear deficiency in our yearly budgets. Our agricultural model farms, though non-paying because of the expensive superintendence accorded to them, have taught us at least this lesson—that land in India, even inferior land if well developed, will yield at least four times as much as it is now doing. We need only give the cultivators a helping hand at first by the introduction of a sufficient water-supply and better implements, and they will soon find out for themselves which system of agriculture is most likely to be for their profit. Look how the manure of the cantonments and city is now considered so valuable, that contractors are glad to take the carting contract. Who could have prophesied a few years ago that such a revolution could possibly take place in the mind of the Hindus of Poona—a city the most unwilling of all the cities of Western India to introduce any new custom. We have only to show that any change will prove remunerative, and we shall find no difficulty in securing its introduction into India. It may be a slow process at first; but in the end success is certain. If this country is brought under the legitimate influence that must come from its being opened up to the progress of civilisation, its development in every department of production and industry must make astonishing progress. Those who help forward this development deserve to rank among India's truest friends.—*Deccan Herald.*

A NEW NARCOTIC PLANT.

MAJOR R. STUART, writing from Port au Prince, notices a very singular plant of that locality. The knowledge of the plant is confined to a few families, who transmit the secret as an heir-loom from generation to generation, and the heritage is highly prized, as it is looked upon as conferring the power of working miracles. In the hands of a skillful practitioner it will produce coma of any intensity or duration, and even death itself, if so intended. The plant, he assures us, is in many ways used in aid of solemn imposture, superstition, and even crime. The power thus used is called "wanga," a word that inspires the African with awe and dread, as he believes this power is obtained from the arch-enemy of mankind. The common method of showing its power, or, more correctly, the mode the wanga priest adopts to exhibit his power over persons, is to administer a little of the drug, by which the subject is thrown into a death-like sleep, and, knowing the symptoms of returning consciousness, he will make a show of recalling to life. If a burglary is to be committed, he can, by means of his art, cast a deep sleep on all in-doors; and one can understand how he can attain other forbidden ends in the same way. An experienced botanist could not fail to discover the plant, which, as an anæsthetic, would, no doubt, prove a valuable acquisition to medical science.

A NEW FIBRE.

IN the Paris Exhibition was shown a sample of a fibre named Malachra rotundifolia sent from Bombay. This plant is, however, only found in South America—at least so says Dr. King, to whom the supposed Malachra rotundifolia was sent for identification, and he states that it is Malachra capitata, not Malachra rotundifolia. As a fibre, be it what it may, it undoubtedly deserves attention, for it is said to be quite equal to jute. The following is the description given of it:—"The fibre is in length 8ft. to 9ft., has a silvery appearance, with a peculiar lustre, and is almost as soft as silk. In passing the fibre through the machinery damped with oil and water as is commonly done with Bangyl and Koukan jute, yarn was produced strong enough and nearly equal to that made from the second quality of Bengal jute. If the plant is carefully grown and well looked after, the fibre would then no doubt rank fully equal to Bengal and Bombay jute. Owing to the high prices ruling for jute in Bengal and elsewhere, the new fibre, if carefully prepared, would command a ready sale at Rs 3-12 to Rs. 4 per Indian maund." There appears to be no difficulty in growing this plant, which belongs to the natural order of Malvaceæ in Bengal, marshy places within the tropics being considered favourable to its growth, and there is, therefore, every reason why a fair trial should be made of its apparently valuable properties. The fibre is prepared in precisely the same way as jute, but requires to be steeped directly it is cut, as exposure to the sun dries and hardens the stems, preventing the easy removal of the bark from them, and rendering the fibre itself coarser in quality than it would otherwise be.

THE RUBBER TREE AND AFRICAN PALM.

A FEW years back many were supposed to be wasting money on cinchona plantations. Those who sneered and had doubts would, I dare say, be glad to possess a few acres. So in the same way there will be many who will regret that for the sake of a few rupees they did not experiment with other new products. The lands in the high regions of the country are now turned to use, even cocoa planting is making progress in the lower elevations of the hill country. It is very doubtful though whether the natives will take any interest in the products suitable to their lands. Rubber tree could be grown cheap, but what they will prefer would be the African oil palm, as the plant will grow with little or no attention. Of course the native gentry should give the impetus, instead of wasting time in the vain cry to Government to aid and secure prosperity for them. Both these products and even cocoa will cost them *less* than cocoa-nut planting, and give them more profit and in half the time! Of course intending growers should secure seed, and it is preferable to get them from the country they grow. There is a specimen of the palm nut at the Botanical Gardens and some are said to be in Jaffna, but a gentleman who has seen them, says they are not the best of the kind and are known as "bastard palm" growing wild like our wild plantains and wild sugar-cane. Of the rubber tree there was a specimen on the Academy grounds that yielded really good rubber; if the tree still exists the seed should be collected. It was a common practice when low lying coffee estates were opened up, to plant along the bounderies and roads and on the edges of ravines areca-nut palms and occasionally Kittul. It is hard to judge with what object, but the planting of the African palms by those opening Liberian coffee and cocoa estates in a similar manner would lead to profitable results, the first fruits would sell in the Island well as seed. In the estates I refer to, nearly all the coffee is abandoned, but the areca-nut and other palms are there, living and bearing as usual. Planters in Mulala Kallura, Kurnegalla and lower Dumbera ought to try their hands at planting these palms. The cost is very trifling.—*Correspondent in Ceylon Times.*

"OUR FOOD SUPPLY."

IN the report on the working of the Sydapet Farm for the year ending 31st March 1879, just issued, some interesting information is supplied of the experiments made there in the cultivation of different descriptions of grain and plants. Appended to it are few papers, one of which, "Our Food Supply," is worth notice. It was drawn up by Mr Benson and submitted to the Famine Commission, the President of which is writing his report in England. In the Madras Presidency wheat, paddy, cholum, cumboo, raggy, and certain descriptions of inferior pulses form the food supplies of the people, and it is calculated that the proportionate area of land used for the pulse crops is 19,931,000 acres. Some of these pulses are considered by competent agriculturists as "little better than unimproved weeds." To support the whole population of the presidency 150 million

cultivate opium, but the *Coree* caste are the most fortunate in their cultivation.

The outturn of the opium per *bigha* varies according to the soil. Very carefully cultivated land Mr. Turnbull says, will produce fifteen seers, but we have been given to understand that twelve seers is the most that can be hoped for. Fifteen is a rare maximum; twelve may be given as a fair outturn of the Benares agency, whilst that of Behar is somewhat in excess of Benares.

The Poppy cultivation can be traced in India to as far back as the sixteenth century. And Mr. Turnbull is of opinion that China is indebted to Nipal for the introduction of the Indian drug; and afterwards by the Dutch who purchased the drug for export long before the East India Company held power in this country.

We will conclude by extracting a small note made by Mr. Turnbull, showing the early date of the cultivation of opium in the Allahabad District. "I am informed in the *Ayeen Akbar* of Abul Fuzul, prepared during the after half of the sixteenth century, it is mentioned that the opium and saltpetre monopolies were in the Sirkars of Korah in the Fatehpūr District, and in Allahabad, and in Ghazipur, and the produce of the opium monopoly was 1,000 chests."—*Indian Herald.*

OPIUM CULTIVATION IN BEHAR.

It would appear that opium cultivation is not so very profitable in Behar as is ordinarily supposed. During the year 1878-79, the average yield per beegah in the Behar Agency was 3 seers 15¼ chittacks, and though this average was a little higher than in the previous year, the yield represented in money, at Rs. 4-8 annas per seer of opium of the highest consistency, is about Rs. 18. The average yield in the previous year was 4 seers 5½ chittacks, which, in money value, repesents about Rs. 24-8. The average rent for poppy lands is Rs. 8 per beegah, and taking the cost of cultivation and other incidental costs to be Rs. 3, the profit left to the cultivator is only Rs. 4 to Rs. 5 per beegah. The risk and trouble, however, are great, and it is in some measure inexplicable why people take to the cultivation at all. One explanation suggests itself by reading the Government Resolution published in the *Calcutta Gazette* of the last week. For a people with whom chronic indebtedness is the rule, advances are great baits; specially as these advances are so timed that the landlord's arrears of rent can be met from these advances. The landlord classes in Behar, are, we suppose, most in favour of their ryots taking to poppy. It brings them higher rent, and the system of advances makes the cash rent easily recoverable. The advances and prices paid at the agencies to the poppy cultivator for the most part find their way into the pocket of the landlord, and the ryot does not find himself richer at the end for all his troubles and expenses. With a bad season there is some difficulty in recovering these advances, and we find that, out of the outstanding balances of 1877-78, about 2½ lakhs still remain to be realised, and in 1879, the outstanding balances in the Behar Agency amounted to Rs. 99,572. There is, however, some evidence to show that the cultivation of poppy is not popular. In 1879, the orders of the Government of India directed that efforts should be made to increase the cultivation in both Agencies, but in the Behar Agency the increase in the settlements was but small.—*Behar Herald.*

THE SAIDAPET EXPERIMENTAL FARM.

The report on the working of this farm for the year ending 31st March 1879, has just been sent to us, and we are now at the end of April 1880. Thus, in one respect, the last petted child of Government has learnt, at a very early age, to walk in the footsteps of its brethren. We must not, however, blame the Superintendent in charge solely, for we see that his report is dated the 3rd May 1879, or just one year ago, save four days. Mr. Benson forwarded it to the Board of Revenue on the 16th July, who reported upon it on the 28th of the same month. On the 2nd of August, he appears to have sent to the Board the annual report of his department on Government Farms, and the members must have been taken aback on on seeing its bulk, for in their order they observe that "they take the opportunity to remark that the reports issued by the Superintendent might, in all cases, be condensed with advantage. The same amount of information could be given in a much briefer space." Brave! ye members of the Board. The fact is, as we have observed frequently, officials are far too fond of writing long reports. If they had really anything to tell the public of which it is not aware, a long report might be tolerated and accepted, even with thankfulness, but when they are made up of twaddle and extracts from previous letters and reports already published, it is necessary for some one to see that unnecessary expense is not incurred in their preparation and publication. The report before us deals speciall; with the working of the Experimental Farm. The Government order is dated 9th October last, *i.e.*, more than six months back. Shall we be considered too inquisitive if we ask, why it was not sent to us last November? If we were bidden to describe the nature of the order, we should say it is one of a negative description; unlike Balaam, the Government appear to have been inclined to bless, but their remarks partake very much more of the nature of a curse. For instance, we read that the success of the operations on the Farm was affected by a somewhat abnormal season. The crops suffered from fungoid diseases and rats, and it is suggested that the increase in the number of the latter may be due to the too great destruction of snakes. The outturn of the crops generally was not good. Again the Government very naturally observe with regard to the financial results, that, in the absence of all details as to the manner in which the estimate is arrived at, no opinion of the accuracy of the value of the estate and dead stock, which is estimated to have materially increased during the year, can be formed. The last para of the order we give in full:—"A serious falling off is again reported in the value of the farm cattle, and explanation must be afforded. The illness and death of the Australian cows is shown by Mr. Western to have been in all probability, due to preventible causes, and his remarks must be borne in mind, in the treatment of any foreign cattle that may hereafter be bought."

We presume that the whole and sole object for which the farm is kept up, is to prove to the native agriculturists how, with superior modes of cultivation, it is possible to increse the produce of the land in this country, without incurring any very great addition to the expenditure. If we be right in our surmise, then all we have to say is that the farm is a miserable failure. Indeed, whether we judge the working of the farm in accordance with the financial results obtained, or in any other way, it is impossible to, arrive at any other conclusion than that it is a sham and delusion. We have to test it by the rupee-test, but unfortunately we have not all the figures before us to enable us to do so thoroughly. We have, however, sufficient to show our readers what an absurdity it would be for any wealthy ryot to attempt to follow the example set him by the managers of the farm. On turning to the statement of the accounts for the year 1878-79, we find the receipts set down at Rs. 2,589, while the expenditure amounted to Rs. 12,181. A pretty state of things to ask our ryots to imitate, verily. But when we examine into the items of which these sums are composed, we have yet further reason for wonderment. There was spent for the purchase of grains and seeds Rs. 733. Now how much do our readers suppose was obtained in return from the land, which was treated in the most Scientific manner after the teaching of Cirencester? As they cannot possibly guess, we at once mention the amount, *viz.*, Rs. 217 The land does not appear to have given its natural increase, as we are taught to expect in a certain old book. On the contrary it yielded just about a third of the value of the seed put into it. About the Live Stock we shall have something to say presently. The expenditure under that heading is set down at Rs. 3,083, the receipts at Rs. 264!!! The total receipts and expenditure of the farm were in the proportion of five rupees spent to one rupee got. The figures connected with the valuation of the Farm, are equally significant and equally disappointing. We have nothing given us to show how much has been sunk in previous years. We merely find set down under the heading Estate, that the lands, buildings, wells and channels were *valued* at Rs. 66,230 on the 31st March 1878, and that they increased in value during the year by Rs. 470. But whether the increase of Rs. 470 is attributable to money spent on capital account is not stated, though we presume it was, as we find the value on the 31st March 1879 set down at Rs. 66,700. Under the heading Farm, we see it noted that the value of the cattle *decreased* by Rs. 990 during the year, and that of the sheep by Rs. 105; the pigs and poultry showed a slight increase. The one large increase observable in these accounts on the right side is Rs. 3,435 under the head, Fruit and Fuel Trees But what, in the name of wonder, has an experimental farm got to do with the cultivation of orchards? Why should the Saidapet Farm usurp the place so long and so well occupied by our Agri-Horticultural Society? By adding in this sum of Rs 3,435, whoever drew up the accounts had succeeded in showing an increase in the value of the entire estate during the year of Rs. 3,004. If it be omitted from the accounts then the farm, instead of improving, deteriorated in value during the year under review. In spite of what the Superintendent tried to prove, the season was not an abnormal one; at any rate if he chooses to describe it as such, perhaps, he will explain to us, why the ryots all around Madras succeeded in obtaining good average crops.

Let us take section four, headed Live Stock, and see what the farm did in the way of keeping cattle for dairy purposes. Two cows were purchased that had been imported from Australia. Rs. 200 was the price paid for them, or say double the price of Nellore cows. They were bought in December 1878, and they quitted this life, deeply regretted, in February 1879. Why they died no one knows; they were not poisoned, at least so says the Assistant Professor at the Medical College. During the time they were alive, they yielded 656 measures of milk worth Rs. 109 and cost for feeding and attendance fifty-two rupees, so that it would appear they were actually profitable so long as they lived. But this is not the kind of account the public cares for What is wanted is for the Superintendent to take a Nellore cow, let us say, to note the exact cost of its feed during a full year and the exact return it gives in the shape of milk, the value of its calf if it have one, and to find out what is the best and most economical mode of feeding it, so as to keep up its milk-supply as long as possible, or until after it has been got with calf. We have kept cattle for years, and if we were only to take the figures connected with their keep for the two or three months after calving, we could

show a first class balance sheet. As it is, though we are compelled to keep a man specially to look after two cows, though we have to purchase every blade of grass they eat, as well as straw, pottu, bran, and poonac, we can still show a small profit at the end of the year in addition to the value of a calf. We are almost inclined to think that the Government will not be justified in its support of the Farm, if things do not mend very considerably during the course of this year. It may be, of course, that it is conducted altogether on wrong principles to prove a paying concern; but that is just what it ought to prove if it is to be continued. Anybody can show wonderful results with an unlimited purse to go at.—*Madras Times.*

QUININE AS A FEBRIFUGE.

QUININE is admittedly the most valuable tonic and febrifuge ever discovered. Until a few years ago the world was dependent for its supply on certain naturally inaccessible and politically disturbed regions of South America, where the various species of cinchona trees grew wild. Many attempts have been made, sometimes successfully, to introduce this health-sustaining and important plant into different parts of the globe, and we learn that, in San Franciso, the prospects in favour of the successful cultivation of cinchona in the State of California are extremely favourable. The *Bulletin* says:—"The trees, after a start has been made from seeds, are increased by means of cuttings. According to Mr. Morris of Ceylon, returns can be obtained from cinchona plantation at nearly as early a date after planting as from coffee or tea. The best climate is one which has moderate winds and rains, and the tree does best on rich soils. It is reported that the cinchona plantations made by the British Government at Hakgalla, Ceylon, suffered last year from too much rain. An unusually wet season injured and destroyed a large part of the grove. This was partly owing to destructive floods, and partly to the water standing about the roots of the young trees, but many of these have grown again from the base." Experience has shewn that the cinchona grows admirably in Jamaica, some trees in the parish of Manchester having attained a height of twenty-five feet at the age of seven years, growing at an elevation of two thousand feet above the sea. The largest trees we read of are thirty-five feet high, with trunks two feet in circumference and growing in ordinary soil. A few hundred pounds of bark, stripped from these trees, were sent to England in 1878, and sold for forty-five cents per pound. The report of the Government states that the best altitude for cinchona in the island is three thousand feet. It would certainly seem as if the counterpart to the climate of a three thousand feet height in Jamaica could be easily found in the State of California, which may be said to contain within its boundaries almost every known description of climate, from the heat of the tropics to the cold of northern Europe. Besides its valuable medicinal properties cinchona may be reasonably expected to yield a handsome profit in the event of its cultivation proving successful. From the report already alluded to we learn that the bark of *Cinchona Succirubra*, grown in Jamaica, sold in London last year as high as sixty-four cents per pound. A gentleman in charge of some cinchona plantations in the island, writes to Sir Joseph Hooker, the eminent botanist, and states that he cut down one hundred trees of ten-year old *C. Succirubra*. They yielded 1,660 pounds of green bark, which dried to 415 pounds, and sold for two hundred and forty-four dollars. Three hundred trees were planted to each acre, so that cinchona culture has been proved to be very profitable. The wood also is valuable for fuel, and the trees, when cut down, sprout from the stump. Returns once in ten years of over seven hundred dollars per acre, or seventy dollars per year, is worth attention. The plantation on which these results were obtained is to be extended by one hundred acres. This experience is confirmed by Mr. Willis Weaver, of Bogota, who states that profits of $8,000 per acre had been yielded in a few authenticated cases, the bark being of the most valuable species, bringing $1·75 per pound in the English markets. In Bogota, altitude 8,650 feet, temperature 60 degrees Fahrenheit, and where there are heavy frosts, *Cinchona Cordifolia* grows, and even thrives 1,000 feet higher up the mountain side. The true cinchona region varies from 30 degrees to 60 degrees, according to the species, but *C. Succirubra* is not successful in a temperature below 60 degrees and above 70 degrees. The cinchona belt evidently covers 40 degrees extreme variation, and some single varieties have a range of over 30 degrees. On the Andes the oak and walnut grow alongside the cinchona, and the apple, peach, and wild cherry occupy the same range. All these data tend to show that, among the useful foreign plants which the authorities are endeavouring to acclimatize in Japan, the cinchona might well be included, local conditions of soil and temperature being eminently favourable to its growth and propagation."

MINERALOGY.

IT is said that mining enterprise is likely to be checked in certain parts of the Wynaad in consequence of litigation. This has been anticipated for some little time. It was known that the right of ownership of certain blocks was challenged, and that the dispute was likely to culminate in legal hostilities. It is now currently reported that the "fat is in the fire," and that actions and cross-actions are pending. Nothing could exercise a more deterrent effect upon the minds of English speculators than to hear that the legal title to the land was doubtful. For this and indeed for every reason, the best endeavours will no doubt be made to settle ground-right disputes by arbitration, and to preserve "peace with honor" among the various claimants. No question regarding the ground is ever likely to arise in the Kolar goldfield, for it was handed over to the *concessionaires* on the plainest terms possible by the Mysore Government.

MR. EDISON, who seems to discover something new every few days, has now invented methods by which he can extract a greater amount of gold from the rejected residuum of auriferous quartz, termed by miners "tailings," than is obtained by the present processes from the virgin rocks triturated by the crushing mills. The agents he employs are chemistry and electricity. He takes a quantity of "tailings," which, so far as any known process is concerned, contain not a trace of gold, and produces therefrom the precious metal in quanities truly astonishing. He says that by his method he has got gold from concentrated "tailings" at the enormous ratio in some instances of 1,400 dols. per ton, at an expense not exceeding 5 dols. per ton. This discovery was made by him while endeavouring to find a supply of platinum for his electric lamps. Keeping the secret to himself and to a few confidential agents, Mr. Edison at once made contracts for the "tailings" of the largest mines for a term of years. He has thus secured millions of tons of "tailings," and if his manipulations of the refuse really prove as valuable as stated, Mr. Edison ought to become a "veritable Crœsus."

IN our last issue we drew attention to the important fact that silver lead ore had been discovered in large quantities in the Hazareebaugh district. We may add now that ten tons of this argentiferous galena are now in course of shipment to England, and small quantities of gold and auriferous quartz have been found in the same locality. Amongst other minerals some specimens of molybdenite have been discovered and left at our office for inspection. This is a very rare metal of peculiar quality and has only been found in any quantity in Saxony. It is imbedded in fissures of limestone between two layers of hornblend. It has not yet been applied to the arts, but was known to the ancients as a valuable chemical agent. It is found in small flaky cakes of a brilliant platinum colour. When reduced to a paste with oil, bedded in charcoal and exposed to an intense heat, it becomes brittle. By heat it is converted into a white oxide which rises in brilliant needle flowers like those of antimony; nitric acid readily oxidizes and acidifies the metal: nitre detonates with it, and the remaining alkali combines with its oxide. A very small particle of the metal is to be seen in our mineralogical museum, and its ultimate use as a metal, if obtained in quantities, has yet to be discovered. This is the first *boná fide* discovery of its presence in India. As previously intimated, we shall have more to say shortly about the working and prospects of these mines.

LITTLE has been said lately about the sapphire mines of Siam, concerning which we heard so much a few months ago. The existence of mines of inferior value has long been known; and about five years ago the new mines were discovered. Owing to their remote situation, it was some time before the news of the discovery reached the Burman and Indian gem dealers. Some fortunate individuals, however, found their way to Calcutta and Rangoon with valuable specimens of the result of their labours. The sapphires brought by them sold

for large sums; and numbers of adventurers at once hastened to take advantage of this fresh source of wealth. Throughout the year 1879, thousands of British subjects from Burmah passed through Bangkok on their way to the mines. The unhealthy conditions of the place, however, proved fatal to numbers of the miners, and although many realised great profits, the rush is now beginning to abate. The only revenue raised from the mines is by a poll-tax of less than six shillings a head. No royalty is paid upon the gems found. The finders of valuable stones are not anxious to publish their good fortune, it is, therefore, impossible to estimate the value of the outturn of the mines. One stone was offered for sale at Chantauboon for Rs. 1,000; afterwards the owner refused Rs. 15,000 for it in Rangoon; and it was finally sold in Calcutta for Rs. 30,000. A sapphire weighing 370 carats in the rough, and 111 carats when cut, is the largest yet known to have been found. Other very valuable specimens have been seen in the possession of persons returning from the mines.

COAL IN BHAGULPORE.

WE have been credibly informed that Baboo Hera Lal's coal mines in the south of this district are now being worked, and that coal is carried to Pathurghatta on the bank of the Ganges near Colgong at something like 3¾ annas per Bhagulpore maund. The coal is at present being used for lime burning, but its use may shortly be extended to other branches of industry. Excellent roofing, and paving tiles were once made at Pathurghatta, and there is no reason why the manufacture of these works should not be revived. Lead mines: About two years ago one Mr. Jones started operations on a lead mine in the estate of Luchmiput Roy in the south of this district, but owing to some cause or other he was obliged to abandon the project. We are told a large sum of money was spent by him for putting up machinery, &c. We are now informed that lead has been found in more favorable localities near Bousee, a place only 32 miles from this station, and is accessible by a first class metalled road. Want of capital is the greatest drawback in Behar; but there is no reason why Bengal should not step in and convert some of its 4 per cent. stocks into working capital to try these mines. Many of the retired men from the Public Works Department would do well to turn their thoughts in this direction.

THE INDIAN GOLD FIELDS.

THE text of Mr. Brough Smyth's report on the Wynaad gold fields was issued last week as a Parliamentary paper. It is an interesting document, giving details of the various reefs, and many practical hints as to the best modes of gold mining. With respect to the extent and character of the Wynaad fields Mr. Smyth states that—

"Gold has been found on the south near Eddacarra, and on the north near Nellacottah, on the west near Vyteri, and on the east as far as Bolingbroke—that is to say, over an area of more than 500 square miles. The reefs are very numerous, and they are more than of the average thickness of those found in other countries; they are of great longitudinal extent, some being traceable by their outcrops for several miles; they are strong and persistent, and highly auriferous at an elevation of less than 500 feet above the sea, and they can be traced thence upwards to a height of nearly 8,000 feet: near them gold can be washed out of almost every dish of earth that is dug; the proportion of gold in some of the soils and reefs in the neighbourhood of Devala is large; and, the country presenting the greatest facilities for prosecuting mining operations at the smallest cost, it must be apparent to all who have given attention to this question that, sooner or later, gold-mining will be established as an important industry in Southern India."

It is, however, he thinks, not unlikely that the first attempts to open out the mines will fail.

"Speculative undertakings, having for their object the making of money by buying and selling shares, are commenced invariably by appointing secretaries and managers at high salaries, and the printing of a prospectus. This is followed by the erection of costly and not seldom wholly unsuitable machinery; no attempts are made to open the mine; and then, after futile endeavours to obtain gold, and a waste of capital, it is pronounced and believed that gold mining on a large scale will never prove remunerative. It is probable that this story will be repeated again and again, here as in other gold-mining countries, until some one of the mines is opened by experienced persons who desire to secure profits not by dealing in shares, but by mining."

This warning is not unneeded. The Government of India, it is announced, purpose to authorise the Madras authorities to grant gold-mining leases of Government lands in lots of from one to thirty acres for a term of ten to twenty years at a rent of five rupees an acre, provided that not less than five labourers per acre are regularly employed on *bonâ fide* mining operations in such manner as the Government approve. And in order to attract capital, they do not propose at present to levy any royalty or tax on the industry.

GOLD MINING PROJECTS.

THE *Times of India's* London Commercial Correspondent, writes by the last mail:—

The strong tendency—almost amounting to a mania—for investment and speculation in gold-mining in India is still being carefully nursed. A "private and confidential" prospectus has been circulated of "The South Indian Gold-Mining Syndicate" for the purpose of providing the requisite capital for obtaining a concession of mining rights of the gold reefs on a property situate south of the Neilgherry Hills, upon which Captain W. N. Middleton has reported very favourably. The capital of the Syndicate is only £7,500, and its primary object being the introduction to the public of a large company for the purpose of working the property described by Captain Middleton, the prospect is held out that in four months subscribers for the £1 shares will receive a dividend of nearly £3 per share, exclusive of their interest in the remainder of the property. While the professional promoters are taking the business of Indian gold-mining company making in hand, the leading advertising stock-brokers are "building" those enterprises which are already before the public. Thus we are told that "the almost unparalleled success which attended the introduction of the South Indian and Indian Glenrock Gold Companies has naturally brought to the service a multitude of Gold-mining projects from all quarters of the globe, but the bulk of them, if not all, appear to have received very little support from the public, as those who have hitherto been in the habit of investing in mines have learnt by bitter experience to become descriminating, and the properties which have been offered for subscription lack one very important feature which distinguished both the South Indian and Indian Glenrock Companies, *viz.*, the Government brand as to their merits." After a reference to "the report of the Indian Government upon the gold mines of Southern India," as proving the intrinsic merit of both undertakings, Mr. William Abbott intimates that "the mere butterfly speculators who applied for shares simply to sell at a premium have evidently been entirely cleared off the market, which is consequently in a much more healthy condition. The fully paid (£1) shares of the South Indian and Glenrock Companies can now be bought at £2, and upon such a report from Government they must advance considerably."

ANOTHER GOLD MINING COMPANY.

THE London Commercial Correspondent of the *Times of India* writing on the 16th ultimo says:—

Another Indian Gold Mining Company! The prospectus has been issued this week of the "Indian Grange Gold Mining Company, with a capital of £100,000, in £1 shares, of which 33,000 are taken by the vendors" in part payment of the purchase money. The Grange Estate, it is stated, extends over more than 300 acres, and contains four reefs of auriferous quartz. It is situated within a mile of the properties of the Indian Glenrock and the South Indian Gold Mining Companies. The estimate of profits is made on the usual principles, thus:—

100 tons of quartz crushed per day for 300 working days — 30,000 tons; this at 10 dwts. of gold per ton — 15,000 oz, which at £3-15 per oz., amounts to per annum ...		... £56,250
Deduct cost of crushing 30,000 tons at 12s. 6d. per ton...	£18,750	
Deduct other expenses, say 5s. per ton	7,500	
		£26,250
100 tons per day will yield net profit per annum of ...		... £30,000

which will be equal to 30 per cent. per annum; and, what is more, as "this estimate is based on only 10 dwts. of gold being obtained per ton of quartz, whereas Mr. Harris, late Manager of the Alpha Gold Mining Company, estimates that double that quantity will be obtained from the reefs on the Grange Estate," 60 per cent. per annum may be reasonably expected. The prospectus states that specimens of quartz from the tunnel "excavated by Mr. Harris were collected on the spot by Captain P. G. Watts and submitted to Mr. Brough Smyth, who stated that they were as rich for gold as any he had in the Wynaad District." Now a reference to Mr. Brough Smyth's report, as officially published by the India Office, fails to discover any mention of quartz from the Grange Estate; but the last paragraph but one is as follows: —"Two stamples sent from the Chumberra Estate by Mr. Lamb;

twelve collected from Cherrambadi and Vallery-Mulla ; one from the Orange Estate, sent by Captain Ponsonby Watts ; one from the Eagle Estate sent by George Salmoon ; two from Terriott and Glenmary Estate, sent by Mr. Percy Batty, two from Cheppa Toda, and three from Glenlee Estate, Manantoddy, sent by Mr. J. H. Anderson, were tested, and gold was found in minute particles in fourteen." It seems, therefore, that the statement of extraordinary strength, on which the British public are invited to risk their money, rests at present on the *ipse dixit* of the vendors who are promoters of the company, and whose consideration is 33,000 fully paid shares and £17,000 in cash, of half the entire capital of the company. The publication of the prospectus of this company has created some misapprehension, owing to the name of the Secretary to the South Indian Gold Mining Company, and the Indian Glenrock Gold Mining Company, appearing thereon, and the offices being in the same building as those lately occupied by these two companies. The Directors of the South Indian and Indian Glenrock Gold Mining Companies have issued a statement that the Indian Orange Gold Mining Company is not brought out under their auspices, nor is it in any way connected with them.

PETROLEUM.

THE pamphlet by Mr. Doyle on "Petroleum, its history, origin, and use," was written, its author tells us in consequence of certain legislation on the subject of the inspection and storage of kerosine oil, already carried out in Queensland, where Mr. Doyle now lives, and contemplated in India, to be carried out there as soon as the report of the Committee appointed some time ago shall have been adopted by the Government. The pamphlet is an interesting one, so much so as to cause us to regret that it is so small. Enough is said, however, to establish the author's chief position, which may best be stated in his own words. He asks :—

I. Are the interests of the consumers identi cal with those which public safety demand ?

II. Whether legislation is required to—

(*a*) Restrict the importation of low standard oils ? or

(*b*) Regulate their carriage and storage ?

"In reply to the first, it is only necessary to remark that general measures (of acknowledged merit) for the common weal often require much more than the community can concede; and when the limit of acquiescence is so far exceeded as to become what is usually called a "hardship," it is then only that mutual interests cease to be in unison. In other words more directly to the point at issue—these interests are only identical when any measure necessary to secure the public against the risk of fire does not greatly inconvenience the consumer of the oil.

With reference to the second, legislation hardly appears to be requisite to restrict the standard of importation, for, on the principle of self-preservation, this would be self-adjusting. The danger before and after shipment, the risk during a long voyage, enhanced freight and insurance, would soon induce shippers to consult their own interests, and select the lowest standard consistent with safety.

Leaving the disadvantages of high st andard oils aside, which have been fully set forth, and dealing with the safety they insure in the abstract, it is doubtful whether the danger could be removed in this and other hot countries except by an exceptionally high standard of refinement—practically impossible. For it may be argued, that, since a flashing point of 100° F. is requisite in a country where the temperature rarely attains 80°, even for a few days in the year, it must be 120° or even 150° F. to give the same security in India and Queensland, where the temperature often rises far above 100°.

Under the nearly certain probability that transport by sea and, perhaps, land carriage, would soon find its own minimum point of the safety, the responsibility of local authorities, including those that watch over public safety, would commence immediately the oil landed arrived at its destination. There are special warehouses for the reception of petroleum at the London and Liverpool docks ; and similar precautions are adopted with reference to the same in the principle ports of the East—*isolation*, as in all other combustibles, being the *sine qua non* for safety—the only provision against accident."

The recommendation embodied in the last paragraph of the above will probably soon be carried out in India and Burmah, in accordance with the draft rule submitted to Government some time ago by the Committee which met in Calcutta, the more important of which we quoted in full in a former issue. We may here take occasion to remark that we think that the local Government might take some steps in the direction of providing safe and isolated storage for kerosine oil without waiting for the Government of India. This city being built for the most part of wood renders the need of extreme precautionary measures more urgent than in a city like Calcutta. Already rules have been issued compelling ships carrying kerosine oil to discharge it below the Hastings, one step, certainly, in the right direction. Could not a storehouse be built on the banks of the river near to where the vessels lay to discharge, so that when a ship comes in she could commence discharging at once ? Only small quantities need then be kept in town, and the risk of accident reduced to a minimum. A vacant site between Monkey Point battery and the nearest mill might be found, where a storehouse sufficiently isolated for all practical purposes could be built. The need for such isolation is abundantly clear from the extract we have given above ; and the sooner the suggestions of the Calcutta Committee are carried out in the above, or in any more practicable way the better.—*Rangoon Times.*

FORESTRY.

CASUARINA PLANTATIONS.

ABOUT eight or ten years ago casuarina planting was all the rage among small capitalists in and around Madras, and lands were taken up from the revenue authorities in large parcels for planting this fuels-producing tree. In the Chingleput district some thousands of acres of land were acquired under the tope rules, but the Board of Revenue soon put an end to the system of granting lands, as it was found that applicants got the land for no other purpose than to grow a crop of casuarina sufficient to pay the outlay incurred in laying out the plantations and then abandoned them. Restrictions were placed upon the assignment of lands, and casuarina plantations are not such attractive undertakings now as they were ten or twelve years ago, when whole villages from the municipal limits of Madras on the Ennore road, up to Coromandel, on the route of what is now known as the Buckingham canal, were filled with thickly studded casuarina plantations. The enterprise was not confined to Europeans ; a few Hindoos who were anxious to invest some of their spare cash in remunerative undertakings, formed joint-stock companies, and started casuarina plantations. Two such ventures were registered under the Indian Companies Act, the capital of each being ten thousand rupees. They did not prove successful : the directors were not able to get the capital required, the managing directors grew lax after the gloss of novelty had passed away, and in the course of three years the companies were wound up. At this time between twelve and thirteen thousand cawnies of land were planted with casuarina in the Chingleput district. Of late, however, there has been no great desire to revive the enterprise, and all that is being done in this direction is the work of the Forest Department which maintains large casuarina plantations for the purpose of supplying fuel to the public and the railway companies. That casuarina planting is remunerative and amply repays the outlay incurred in its cultivation is well-known. In the southern parts of Madras a few enterprising people have started small plantations and to these information supplied in the report of the Sydapet Farm for the year ending 31st March 1879, will be of interest. The cost of planting casuarina is very small at the Sydapet farm ; with ½lb. of seed one thousand plants were raised, the cost being Rs. 2 against five rupees a thousand plants, the usual price in the market. Sixty thousand casuarina trees were raised in the farm in the year and four coolies were engaged to prepare the ground, sow, water, and weed for four months ; were 120,000 trees raised an additional cooly only would be necessary. The trees were planted at some distance from each other ; twelve square feet being the space allotted. To protect the casuarinas from the sun, castor beans were planted between them, and it is said that if the first crop of beans turned out well, it would have paid the cost of watering the whole plantation. In planting casuarinas it has been found that, if they are put down too far from each other, the main stems instead of growing straight are liable to fork and produce many side branches. The want of a good stem considerably reduces the value of the tree. It is therefore better to plant them close to each other, giving each tree 12 square feet. 3,630 plants were put down on an acre of land, and the expense incurred was Rs. 49. The most expensive item in casuarina planting is manure and the cost of carting which is set down at Rs. 36 per acre. In some places where it is difficult to get water, the cost is increased to Rs. 100, but after the first year, the expenses are light. The sixty thousand plants put down at Sydapet in 1878-79 will, in a short time hence, give a small return.—*Madras Standard.*

GARDEN.

CULTIVATION OF FRUIT TREES.

DR. JOHN SHORTT, F.L.S., writes to us from Yercaud :—

I have read with interest your correspondent *Observer's* letter in the *Mail* of the 13th ultimo, on "Fruit Trees," and I write to say that the plan of notching fruit trees is familiar to natives of this presidency, and I have seen it practised on the cocoanut, palm, jack, mango, and other trees. When these trees do not fruit, the trunk is beaten with the iron shod end of a rice-pounder, so as to leave circular indentations on the bar to arrest the too rapid flow of the sap downwards, and thus render the tree fruitful. I have seen the cocoanut trees thus operated on about Vellore. As regards jack trees, the natives prefer to weight the forked end of the branches with large stones, and it is no unusual thing to see these trees carrying half-a-dozen or more large stones tied on to them. Thus weighting the tree may possibly have the same effect of arresting the too rapid flow of the sap by the pressure exerted on the bark. Another familiar practice is to give the jack a companion, by planting a cutting of the *Euphorbia Nivulia* or *Ella Cullo* (Tamil) under it, or next the stem ; and it is believed to possess some mysterious power of rendering the jack tree

fruitful. How this is effected I could never ascertain, but the practice is general and believed in. As regards the planting of jack-stones and growing the young plants, several ways are in vogue; one is to plant a whole fruit, and, as the several plants grow up, to tie them together so as eventually to form one single trunk by the union of the many plants that sprout up (Drury.) Another is to encourage the plant to grow lanky under shade, and, when it has attained sufficient height, to coil it into the form of a hoop, leaving the tuft of young leaves above the soil and planting the rest under ground (Firminger.) I generally prefer planting jack stone whilst fresh in nursery beds, singly one season and the following season, just before the rains, transplant them out, and if attention be given them for a while till they are established in their new locality, there is no trouble with them after, except to prevent cattle trespass. The jack wood is highly prized for furniture of all kinds, and has been imported to England. and the dye from it is largely used in Burmah. For full information on these points I would refer your readers to Balfour's Cyclopædia of India, article *Artocarpus integrifolia* in the 1st volume, where much information is embodied on these subjects. The name jack seems to be derived from the Malayalum word *jacka* for the fruit according to Balfour, but Drury says that the name jack is a corruption from the Sanscrit word "*Schackka*" which means the fruit of the tree. The plan of supporting the mango fruit artificially is also well known, and practised to some small extent. The difficulty of reaching fruits at the extreme end of large trees has always proved a difficulty to the natives, and prevents the practice from becoming general, but it is put in operation as regards the pumelow and other fruits, in which the weight of the fruit is cleverly transferred to the surrounding branches by means of straw pads and plaintain fibres. The practice may be witnessed at any time about the fruit gardens at Arcot. As regards "girdling" or rather "ringing," the more correct term, it is well known in English Horticulture by the cutting of a ring of bark from a branch or tree to render it fruitful, but this practice requires a knowledge of the composition of the tree to make it successful, for in no case should the ring cut through the alburnum or sap wood; if this be done, the tree is destroyed. This is what the planter does in destroying the sap wood by ringing, and thus kills the tree to make room for his plants eventually; but how often, from this fact not being known, the tree is rung and still stands flourishing in all its verdure. Examples of this may be seen on the Shevaroys occasionally. As regards fruit trees, should ringing be practised, care must be taken not to cut through the alburnum or sap wood, but only so much of the outer bark as will reach and expose the sap wood, to accomplish which, tact and cleverness are necessary to arrest its too rapid flow downwards.—*Madras Paper.*

ON THE TREATMENT OF HEPATICAS, PRIMROSES, AURICULAS, AND POLYANTHUSES.

THE interest in these early spring flowers, which is yearly on the increase, renders it very desirable that they should be multiplied in numbers as rapidly as possible. No garden in spring can be considered well provided with early flowers if a goodly supply of these be not included in the list of spring flowers cultivated in it. They are among the most showy, profuse, and lasting of the flowers of the season. Complaints are heard in various quarters that they are slow to increase; and, like all really good things, it must be admitted that they cannot be multiplied in the ratio of their merits. But they may be increased with greater rapidity than they generally are, if right methods, and the proper season, are adopted for operating on them with this object in view. A very common error in their propagation is to divide too early or too late. The best time for this operation is immediately flowering ceases, and the plants begin to grow. If done before, and the division necessarily small, there is risk of much loss; and the same will, in all probability, happen, if it is done any time after growth ceases, except it be attended to immediately, so that the divisions may have time to establish themselves perfectly before winter sets in. We prefer attention being given to this point in their culture immediately on growth beginning and flowering ending, which are nearly simultaneous in this occurrence. When divided very small a little sandy compost should be used immediately about the roots to encourage the formation of fibres abundantly; this is especially necessary in heavy loam or clay soil. If the weather is dry at the time of dividing, give a good watering before fully closing the soil in about the roots, and continue to water as the weather may necessitate. When they have established themselves, and are growing freely, they will be benefited by frequent supplies of liquid manure, and from the first after being divided they should be well mulched with leaf mould or manure, to encourage the formation of fibres on the surface of the soil, and retain moisture during periods of drought.—*North British Agriculturist.*

VALERIANA PHU AUREA.

THIS is one of the most effective of spring hardy plants. Its effect does not, however, arise from any showiness of flowers, but from the leaves, which are a deep golden yellow, the finest yellow coloured vegetation, whether in flowers or leaves, that we happen to know for the flower garden. The well-known Golden Feather is quite inferior in effect to it when at its best. Unfortunately, like many other fine things, it has a drawback. It is only fitted to adorn in the spring months. The leaves become quite green when the sun becomes powerful; and when the plant begins to throw up its flower stems, which, being anything but ornamental, do not in the least compensate for the loss of colour sustained by the leaves. Nevertheless, the plant is well worth the attention of all who have to do with spring bedding, for it has no equal in its shade of colour at any season either for massing or lines. It is perfectly hardy and is easily increased by division.—*Ibid.*

TEA.

AS far as we (*Indian Tea Gazette*) have been able to ascertain, we estimate the production of Indian tea this season at 46 million pounds, should no specially adverse climatic influences supervene.

INDIAN TEA CULTIVATION.—The land under tea in Assam in 1878 was 140,146 acres; in Bengal, 32,255; in the North-West Provinces, 5,380; and in other districts 10,980, making a total for British India of 187,961. The total quantity of tea made in all was 36,143,045lb. The average yield in pounds per acre of mature plants was in Assam 286lb., in Bengal 263lb., and in the Punjab and North-West Provinces about 200lb. There are 2,330 plantations in all, of which 850 are in Assam, 235 in Bengal, and 1,174 in the Punjab.

A CORRESPONDENT signing himself PEKOES writes to a contemporary on the present position of Indian tea in connection with the taste for tea as now existing at home, and strikes the nail on the head when he asserts that the consumer at home has not yet had an opportunity of tasting pure Indian tea. And when he has, it has been that class of rasping, pungent, malty tea, made with a view to bolster up China trash, and never intended to be drunk pure. He also speaks of the immense profits which are made by the middlemen at home, and quotes a tea which sells at, say, sevenpence per pound in Mincing-lane, as costing the consumer three shillings per pound, after sixpence duty has been added. This tea then costs 1s. 1*d.* per lb., and as it sells to the consumer at 3*s.*, it follows that somehow a profit of 177 per cent. has been made on it between the auctioneer and the consumer. The manufacturer gets none of this. We think it exceedingly likely that 3*s.* is rather an exaggerated figure for a 7*d.* tea; however, there can be no doubt but that very large profits are made by these middlemen. Even if this tea sold at 2*s.*, a profit of 85 per cent. would be made on it, and this while the individual who ought to make the largest profit on it—*viz.*, the man who has risked his capital in the venture—is finding his capital disappearing gradually from his sight.

To a very large extent the planters are themselves to blame for this state of affairs. They refuse to associate. Were they only to do this, and combine for praiseworthy objects—self-protection among them—such a state of affairs would be impossible, as the Indian tea industry is now of sufficient magnitude to exert an influence and make itself respected in commercial centres. We have written on this before, but it seems of little use. The individual jealousies of each company bulk larger in the eyes of proprietors than do the general prospects of the entire industry, and until the mischief of this is seen, and united action taken, we can hope for nothing in the way of amelioration.

A CORRESPONDENT to a contemporary speaking of the proposed attempt to introduce Indian tea to the Australian consumer, mentions as one of the difficulties to be overcome, the fact that the taste for Indian tea is like that for beer or tobacco, an acquired one, and that it will have to be created slowly. We do not think this is the case to a very large extent. We think this correspondent is only right if he refers to Indian tea as now made for mixing purposes. If this be his meaning we agree with him, and with regard to the taste for this class of tea we believe, moreover, that it never will be acquired by the lover of the genuine beverage. There is tea and tea, and we look upon the production made from the rasping tea of the present day, much as a lover of delicately flavoured tea would regard his cup, if his servant had boiled it for half-an-hour, instead of simply infusing it in boiling water. We find

a steadily increasing local demand for the teas of the Kangra Valley, Dehra Doon, and Kumaon, and this supports our contention that tea if properly made will always command fair prices. These manufacturers do not make rasping tea, simply because they cannot; the *jat* of plant of the Upper Provinces is not suitable for its production; the climate is too cold, and the leaf, wanting the forcing power of the Assam climate, and the richness and strength of the Assam black soil, has not the inherent succulence to qualify it for that process; consequently the planters make a delicately flavoured tea, which is what all tea should be, and which is therefore in demand for private consumption. This tea, if sent to Calcutta, would be sacrificed at auction, where delicacy of flavour is out of fashion, and where little else is wanting but strength and excessive pungency. This fact alone goes to prove that the taste for pure Indian tea is not an acquired one, to the extent referred to in speaking of its probable introduction into the Australian colonies. That the taste for malty, pungent, rasping tea is, and ever will be, one to be acquired we do not doubt. At the same time we have no hesitation in calling this bitter decoction not tea at all, as that beverage is understood by all true lovers of it. In the process of manufacture the fermentation is checked at too early a stage, and this resumes itself as soon as infusion commences; thus we have a decoction such as is known in Scotland by the term applied to boiled tea, *viz.*, *hay bree.*

We would invite those of our readers who are interested in the tea-trade of India to study a letter which we reproduced, in our last issue, from the *Englishman*. The writer draws attention to two salient facts—that the superiority of Indian to China tea is now almost universally admitted, and that, in spite of this, the finer is being still beaten by the inferior article, in the markets of Europe. Does the planters' supineness account for this unsatisfactory state of things? Or is the trade being throttled, so to speak, by an over-plus of middlemen? Or is its progress interfered with by trade-tricks at home? Some assure us that all these causes combine to ensure the failure of one of the most promising of Indian industries: and their explanation is certainly in keeping with the enormous difference between the Calcutta sale-prices, and the prices charged by London retailers. At the beginning of this month some of the Calcutta quotations were six annas a pound—about seven pence. Adding six pence for duty the price amounts to thirteen pence a pound; "yet such teas cannot be bought at home for less than three shillings to four-and-sixpence a pound." Surely, a retail price of two shillings might leave an ample margin for brokers' and other middlemens' profits. To heap on intermediate charges, beyond a certain point, is only to kill the goose that lays the golden egg. A reduction of such charges to the lowest possible limit would benefit the brokers and others as well as the producers and the ultimate consumers—for the obvious reason that it would stimulate demand. But the "tricks" of the trade ought also to be discouraged. To mix good Indian tea with China rubbish—as is done by the retailers at home—is not exactly a process calculated to enhance the reputation of the former. Curiously enough, some of the planters are themselves the greatest offenders in the matter of "mixtures." Again, as regards the Kangra valley, and some other localities in the Western Himalayas, the planters are certainly more deficient in *esprit de corps* than is compatible with their true interests. What have they done to establish their footing in Kurrachee,—the route by which is by far the shortest and cheapest to the markets of Europe? And what have the Indian planters, as a body, done to get themselves directly and properly represented in London itself? Almost nothing.

It seems that the past year has not been more favorable for Indian tea cultivators than for Ceylon coffee planters. According to published returns of Assam and Cachar tea companies, their yield per acre has been far less than in previous years, and whilst the cost per lb. of the article produced has been greater, the price realised at home has been less. So large a portion of Indian teas are the produce of plantations owned by companies who publish their accounts yearly, that the position of the tea industry of India and its actual net results can be gauged with tolerable accuracy; this is not the case with coffee in Ceylon where, however, we are able to gather a tolerably accurate idea of the prosperity of the coffee enterprise from facts patent to most of us. In strong contrast with the working of Indian tea companies are the latest annual reports of Ceylon Coffee Companies, and bad as are the times in reference to coffee production, we shall be surprised if the next accounts of the Ceylon Companies do not shew very satisfactory results.

Of the 300,000,000 of population of China and it dependencies, every man who can anyhow afford it, drinks tea morning, noon, and night. The area of unoccupied land suitable for tea-planting is practically unlimited, and as, of the tea planted, much remains unpicked every year, it may be presumed that the cost of the beverage is not much hindrance to tea-drinking among almost all the entire adult population.

The price paid to the China tea grower, for the raw leaf, is $\frac{3}{4}d.$ a lb., and it is estimated that the cost of picking, firing, packing, inland freight and duty, export duty, and freight and charges to London or New York, is not less than 8*d.* per lb of teas.

The Tea Planters' Difficulties.—Our tea planters are constantly having impressed upon them the necessity of studying quality more than quantity in their produce; but it seems to be an uncertain matter as to what quality will suit the tastes of the London buyers. Messrs. George White & Co., in their last circular, tell us:—"The tastes of the trade have for many years been changing, but we believe that if certain gardens could guarantee a supply of good standard tea of uniform quality, and in sufficient quantity, many retail men would prefer to buy such marks regularly, rather than be continually changing their mixtures, as they do now-a-days by purchasing little lots of six or eight chests at a time, which they find it difficult afterwards to match."

The *Indian Tea Gazette* says:—We hear from two or three quarters in Assam and Cachar bitter complaints about the nefarious habit which some men indulge in, of enticing away and harbouring other men's laborers. We have before dwelt on this subject, and can only repeat that we consider intentionally and knowingly taking away a brother planter's coolies to be quite on a par with, and as bad as, stealing his purse. Why don't the right-minded planters in a district where this sort of thing prevails try the effect of a little lynch-law on any notorious offender.

It must be satisfactory to Indian planters to see the Press of Australia interesting themselves in the question of the introduction of their teas into the local markets, even though its zeal in the cause is qualified by some misgiving. All that is necessary to ensure success in the enterprise is, we are convinced, a certain amount of mutual accommodation, combined with the removal of mutual misunderstanding, and the more the question is discussed in a spirit of fairness, the more likely this is to be attained.

After quoting our article of February 13 on the subject, the Melbourne *Daily Telegraph* goes on to say that it sees and acknowledges the force of our arguments, and on purely national grounds would like to see Englishmen in India "participating in the first hand advantages now enjoyed by the Chinese planters." "But," continues the writer, "there are two serious obstacles very difficult to overcome. The first is prejudice, and this, at present is not in favour of Indian teas. Like olive eating, the liking for tea grown on the Indian hills is an acquired taste. We are told, and we feel sure with truth, that no other teas are so pure, but while their purity is kept intact they must also be made pleasant to palates accustomed for generations to China teas. The other difficulty is the price, and this is the most insuperable. Indian teas are far more expensive, and when the simple query is put, why should we pay more for an article we do not like, while we can get what we prefer for less money? we do not find it easy to frame a cogent reply. If Indian teas can be grown to suit our taste, and put on our markets at equal to Chinese values, they will inevitably command a share of our trade, instead of being restricted, as at present, to the requirements of a few epicures."

Now one of these objections, that of cost, is based on pure misapprehension, for, though Indian tea is, no doubt, weight for weight, dearer on the average than its China rival, it yields so much stronger a liquor, and consequently can be made to go so much further, that in the end it is considerably cheaper. As to the objection that Indian tea is unpalatable to tastes not habituated to its use, though it is no doubt true as far as it goes, it is one which will disappear with time and management. Given the opportunity, the taste, in nine cases out of ten, is rapidly acquired, and when once acquired it is not easily lost. The difficulty lies in making a beginning; and this difficulty is to be overcome by that process of admixture which has succeeded so well in England.

According to all accounts the Australian market should present a specially good opening for Indian teas, for the simple reason that the China teas exported for Colonial use are exceptionally poor.

There is good reason, we think, for hoping that the tea syndicate lately formed, will be able to do much towards promoting that mutual accommodation between the Indian planting interest and the trade in Australia which is an indispensible condition of success in the attempt to introduce our teas into that colony. The objects of the syndicate, as we understand them, and as set forth in their programme, are to enlist the interests of those already in the trade in the promotion and extension of the consumption of Indian teas, or, to quote the words of their circular, to interest produce brokers and tea dealers in the extension of the trade, and to arrange with them for mixing and blending teas, &c., &c." It is not the wish of those interested to promote opposition, but rather to solicit the support of the colonial dealers, and it is the general opinion that the scale on which the syndicate will be in a position to conduct its operations will ensure a fair trial for Indian teas in Australia. They will then stand on their own merits, and, if appreciated, the object for which the syndicate has been formed will have been accomplished, and the trade will flow into the regular channels.

We understand that, in addition to sending down a special agent of their own, it is the intention of the syndicate to appoint an influential house in Melbourne to represent their interests, and to assist with their influence in carrying out the object in view.

The movement has been responded to most cordially by proprietors of gardens, and a large quantity of tea has been placed at the disposal of the committee, to be bulked and blended in such a manner as to render the consignments suitable to the Australian market, the proceeds of sales being divided *pro rata* according to an independent valuation of each parcel before bulking.

The expenses of the representative will be paid by the syndicate, and, with the contributions of tea received from all interested to be sent down for sale, the operations of the syndicate will be on such a scale as could not possibly be undertaken by private and individual enterprise, and it is gratifying to see the cordial unanimity with which the tea growers of India have recognised the necessity of opening up new markets for their produce.

There is no reason why a similar effort should not be made to introduce Indian tea in America.

WE learn that 2,000 lb. of Ceylon tea, recently sent to Melbourne sold—two-thirds of the quantity at 2*s*. per lb., and the other third at 1*s*. 6*d*., prices which must be considered very satisfactory in a new market. We may notice that the Customs duty on tea and coffee in Victoria, New South Wales, and South Australia is 3*d*. per lb., in New Zealand and Tasmania, on the other hand, while it is 3*d*. on coffee it is 6*d*. on tea; in Queensland both tea and coffee are taxed 6*d*. per lb. In Western Australia coffee is charged 1*d*. and tea 6*d*. per lb. at the customs.

OPENING OF THE MACAO TEA SEASON.

IN connection with the opening of the Macao tea season, the *China Mail* draws attention to the ever-recurring tendency to over-do this article as to the prices first paid for it. It is said that the usual excessive rates have been paid for the earlier samples; and this fact might be accepted quietly if it merely affected those immediately concerned. The policy, however, of rushing up prices of first shipments tends materially to damage the chance of obtaining tea at anything like reasonable rates; and the same system blindly followed year after year results only in profit to the native tea men, who chuckle and laugh in their capacious sleeves at the want of "nous" and entire lack of combination displayed by the foreign buyers. The latest telegrams, referring to the last shipment of Congou for the season 1879-80, do not favour the notion that the tea brokers at home are likely to follow in the wake of tea buyers on this side. Common Congous, which had been selling for 9*d*. per lb., had declined to 7¼*d*. Such a decline, when it affects any other article in the Home market, produces corresponding caution and prudence at this end of the line; but the effect is but too frequently of a different kind in regard to tea and silk. There is every reason to believe that much of the success which has attended business during last season was owing to the combination, such as it was, organised by foreign buyers before the opening of the various tea markets in China. It is sincerely to be wished that the same course will be followed this season, with a like favourable result.

NOTES ON THE COMING TEA SEASON.

(Foochow Herald.)

THAT the successful outturn of tea shipments from this port in 1879-80 was due in large measure to the self-restraint and pre-concerted unity of action exercised by buyers is now, we imagine, a generally recognised fact. And it must follow, that, unless corresponding action be at once taken, the opening of the new season will prove less favourable than the preceeding one, if not positively disastrous.

It is perhaps unnecessary to remind our readers of certain threatened political complications which may at any moment develope into powerful agencies of disaster. But, apart from purely political considerations, there is another element of danger in the almost absolute certainty that teamen will, in the ensuing month, bring forward a superabundant supply of leaf. These unfavourable conditions may, however, be converted from a factor of loss into one of gain by an early consensus of opinion, made formal and binding on all buyers, to the three following points:—

First.—Market not to be opened before the 1st July.

Secondly.—Not over Tls. 20 per picul to be paid for any Congou tea.

Thirdly.—Buyers to engage not to ship tea on Chinese account.

Let the foregoing points be made sufficiently binding, and stocks will assuredly accumulate. Teamen will then be at the mercy of foreign buyers and supplies on the London market will not necessarily be squeezed dry of all profit by the Chinese seller. But should foreign buyers rush madly in, and a wild competition ensue, as in former years, the course of the London market may be predicated with absolute certainty. The same old causes must produce like unsatisfactory results. Scores of millions of pounds weight will be thrown upon the London market in the first two months of the season, and telegraphic advices of the rest of the crop being already afloat, will infallibly induce the usual haste to realise, and the hindmost must then, as in former years, come off second best.

It may be urged that the hardest thing in the world is to do *nothing* in a masterly manner, and that this sore task would be the lot of the Foochow *chaahszes* during the months of May and June if our advice as to united action were followed. But those who would grow rich must keep cool, otherwise, it will be the old story of a bad season:—with the auctioneer's hammer rapping out, as the sequel, over the furniture of "the house," a fresh verification of the truth "United we stand; divided we fall."

THE TEA PLANTING INDUSTRY.

THERE seems but too much reason to fear that we are approaching a critical period in the fortunes of teaplanting in India. The margine of profit is rapidly and surely nearing the vanishing point; and, though planters surely may still do something to improve the quality, and diminish the cost of production, of their outturn, there is every prospect of the result of their best efforts in this direction being more than neutralized by the growth of competition among producers. It is not only that the outturn of the Indian gardens is steadily increasing, but new competitors are entering the field on all sides, and with demand lagging behind supply, the low cost of production in China is beginning to tell on prices in a way which it never did before, when there was room for all in the market. At such a juncture, it tells cruelly against the ability of the Indian planter to hold his own that he is heavily handicapped by restrictions from which his rivals are free. Indian labour is usually regarded as cheap labour, and the time is within memory when the Indian tea-planter looked to its cheapness as a guarantee against the competition of countries which have now established themselves in the field. No doubt, Indian labour, when left to the operation of natural laws, is still cheap labour; but this cannot be said of Indian labour in Assam. There, after making every allowance for the remoteness of the province from its recruiting grounds, and for the disamenities of the climate, both of which, under any circumstances, would add materially to its cost, it is extravagantly dear. We trust that it is in an opportune moment that the Indian Tea Districts Association has come forward with a strong memorial to the Viceroy on this important question. The Association point out, on the one hand, that the true remedy for that insalubrity of climate from which Europeans and natives in Assam alike suffer, lies, not in imposing vexatious restrictions upon immigration, but in the re-peopling of the country and the reclamation of its waste lands and, on the other hand, that such risk to health and life as this operation must necessarily involve, is insignificant in comparison with the direct morality and wide-spread lowering of the standard of vitality which result from over-population in other parts of India.—*Englishman.*

TEA IN JAPAN.

SOME time since a correspondent asked us to obtain certain information regarding tea matters from Japan. Through the courteous assistance of the Editor of the *Japan Herald*, we are able to state as follows:—Foreigners in Japan have nothing to do with the tea until it is brought down to the Treaty ports. There is, therefore, no opening whatever for a tea-maker; and no foreigner is allowed to interfere with the manipulation. The tea plant was originally brought to Japan from China, but appears almost from its long acclimatisation, to have changed, to a certain extent, its character. The product is gradually increasing. In 1873-4 it was 17 millions. This last amount is, however, an excessive one, caused by there having been a short stock in America and there were consequently an increased demand of high prices and a corresponding tendency to ship there direct. This tea is all *green*, and the entire crop is taken in America. The area of ground occupieds by tea gardens is unknown, probably, even to the Government, a no return of their extent has ever been published. The gardens are generally farmed or let out,—the lessee taking the crop of leaves. The tea is brought down to the open ports in a half-prepared condition. It is purchased in Yokohama, in large or small lots as it arrives, by the European tea-tasters and then is re-fired, colored, and packed under foreign supervision. A considerable quantity of coloring matter is used in the preparation. The tea season commences in May, and before this nearly all the tea-tasters of Yokohama take a run over to America to ascertain the latest tendency in the public taste, in order to regulate the firing, coloring, &c., accordingly. The cup quality is thin, but delicate in favour; whilst the leaf is rough-looking, and wanting in make. The Government do not own any tea gardens, but they have given a certain amount of assistance to an attempt which has been carried on here for the last two or three years to make *black* tea for the European market. This tea was said in many respects to resemble Indian tea, and

several of the Japan tea-men being favorably impressed with it, when it first made its appearance purchased small quantities and sent them to London; but the opinion there was decidedly adverse to the new experiment, and nearly all of the shipments lost money. For the last two years the Japanese have tried the same experiment on their own account, but with equally unsatisfactory results, and the losses incurred are said to be heavy.

THE TEA CRISIS.

THERE seems but too much reason to fear that we are approaching a critical period in the fortunes of tea planting in India. The margin of profit is rapidly and surely nearing the vanishing point; and though planters may still do something to improve the quality, and diminish the cost of production of their outturn, there is every prospect of the result of their best efforts in this direction, being more than neutralised by the growth of competition among producers. It is not only that the outturn of the Indian gardens is steadily increasing, but new competitors are entering the field on all sides, and, with demand lagging behind supply the low cost of production in China, is beginning to tell on prices in a way which it never did before, when there was room for all in the market. At such a juncture, it tells cruelly against the ability of the Indian planter to hold his own, that he is heavily handicapped by restrictions from which his rivals are free. Indian labour is usually regarded as cheap labour, and the time is within memory when the Indian tea-planter looked to its cheapness as a guarantee against the competition of countries, which have now established themselves in the field. No doubt, Indian labour, when left to the operation of natural laws, is still cheap labour; but this cannot be said of Indian labour in Assam. There, after making every allowance for the remoteness of the province from its recruiting grounds, and for the disamenities of the climate, both of which, under any circumstances, would add materially to its cost, it is extravagantly dear. For this extravagant dearness the Government alone is responsible, and it has now become a grave question for the Government whether, for the sake of all concerned, of the cooly as well as of the planter of the public revenue as well as of private interests, it will by a revision of its labour regulations, give the tea enterprise a new lease of life, or whether, from a one-sided view of its duty, it will elect to hold its hand and see the industry die out.

We trust that it is an opportune moment that the Indian Tea Districts Association has come forward with a strong memorial to the Viceroy on this important question.

The Association point out, on the one hand, that the true remedy for that insalubrity of climate, from which Europeans and natives in Assam alike suffer, lies, not in imposing vexatious restrictions upon immigration, but in the repeopling of the country and the reclamation of its waste lands, and on the other hand, that such risk to health and life as this operation must necessarily involve, is insignificant in comparison with the direct morrality and widespread lowering of the standard of vitality which result from over population in other parts of India.

Taking this reasonable view of the case, they question whether a certain amount of direct expenditure might not be beneficially applied in promoting immigration into Assam At the same time they urge the necessity of a general revision of Act VII. (B. C.) of 1873, in the direction of greater simplicity, and, pending such a revision, of dealing promptly with certain points of pressing importance. These are :—

First.—The extension of the maximum period of contracts from three to five years.

Secondly.—A simplification of the regulations and conditions attaching to recruitment in the labour districts, with instruction to the local officers to co-operate in a friendly spirit towards smoothing the difficulties which stand in the way, thus reducing the cost.

Thirdly.—That the influence of the Government be exercised to induce the rulers and sirdars of the quasi-independent territories bordering the ordinary recruiting districts, to remove the impediments which stands in the way of free emigration from such territories, under a guarantee that the emigrants shall receive the same degree of protection as those drawn from our own districts.

Fourthly.—If the scale of diet and medical comforts prescribed for the immigrants while on board the river steamers in transit, shall not have been simplified and reduced in cost, as the Association understands, was in contemplation by the Government, that such may be done.

They further add their opinion that it would tend towards greater regularity and economy if the obligation to provide diet, medical attendance, and sick comforts, were transferred from the employers to the steamer companies as forming part of their contract as carriers.

The considerations which argue in favour of the first of the above concessions are almost too obvious to stand in need of comment. Not only is the term of three years absurdly short, when compared with the initial cost of the cooly, but it is only towards its close that he becomes thoroughly acclimatised, and the planter begins to reap the full value of his services. The fourth point, we believe, has already engaged the attention of the Government. The desirability of the other reforms asked for is scarcely less obvious, though the practical difficulties in the way of their realisation, will probably prove less easily surmountable.

THE TEA SYNDICATE.

THE following circular has been issued by the Calcutta Tea Syndicate :—

It has been suggested to the Committee of the Syndicate, by Planters and Proprietors, that many Public Companies and Private Concerns are desirous of co-operating with the Merchants and Agents of Calcutta, who have subscribed to the above object, by forwarding consignments of Tea for disposal on their account at the best price obtainable in the Melbourne market.

As such consignments would materially aid the object in view, and enable the Syndicate to carry on operations on a much larger scale than could be attempted if the business were restricted to the amount of subscriptions in cash, the Committee would request the favor of your assistance in arranging with the estates under your agency for such consignments as they may deem expedient.

The representative appointed to proceed to Melbourne, Mr. D A. Sibthorp, is a professional Tea-taster, who has had long experience of both the London and Calcutta markets and in the Tea-growing districts, and is also believed to possess the business qualifications essential for the establishment of the trade.

He will enter on his duties in Calcutta in June next, and proceed to Melbourne in August, so as to arrive there in good time to make all preliminary arrangements before the opening of the exhibition in October.

During his stay in Calcutta, he will be prepared to receive through the Calcutta Agents of Gardens, consignments of Tea, and arrange for their shipment under the direction of the Committee.

It is well-known and admitted that one of the causes operating against the more rapid extension of the consumption of Indian teas in England, is the immense variety in the classification and the quality of the Teas offered for sale throughout the year, and the consequent impossibility of retail dealers obtaining the same standard continuously. It is, therefore, in the opinion of the Committee, most important that the tea shipped to Australia by the Syndicate should be of a description that can easily and at any time be repeated if orders be sent up by dealers and others.

In order to secure uniformity in quality and appearance as far as possible, and thus create a demand for that class of Tea which the Committee are informed is most in request to Australia, it is proposed to bulk the Teas from the different districts before shipment, classifying them under the descriptions of Assam Teas Darjeeling Tea, Cachar Tea, &c., samples of which will be retained here by the Syndicate for general reference. The Teas thus bulked to be shipped under the Syndicate mark.

The detailed instructions given will, to a great extent, secure a degree of uniformity in the Tea forwarded, but to guard against the possibility of the interests of any one shipper being affected by the bulking together of Teas of different quality and price, it will be the duty of Mr. Sibthorp, in concert with the Calcutta brokers to carefully inspect and value every parcel, and to set aside for bulking only those parcels which according to their judgment are considered suitable.

The proceeds of sales will be returned to the various contributors of Tea in proportion to the value fixed on each parcel before bulking.

The advantages of this course are not confined to the better opportunity thus afforded of establishing a large trade in the class of Tea most in demand in the Colonies, but it also ensures that unity of action and identity of interests so essential to success.

The Merchants and Agents of Calcutta have subscribed about Rs. 20,000, and the Government of India have been pleased to sanction a grant of Rs. 10,000 towards the expenses of the undertaking. It now remains for proprietors to give their co-operation to the common object by consignments of Tea to be dealt with as proposed above, and although sales in Australia, to begin with, may not result so favourably as sales in Calcutta or London, the difference should not fall heavily on any individual Garden when only a few chests are sent from each, and a combined effort on such a scale will probably be of great ultimate advantage to all interested, by creating a demand that may divert a considerable quantity of Indian Tea from the overstocked market of London.

Particular attention is requested to the instructions given regarding quality, packing, marking, &c., and all consignments should reach Calcutta not later than the end of June, in order that Mr. Sibthorp may have plenty of time to arrange for shipment; but should any parcels arrive after Mr. Sibthorp's departure, the firms of Brokers who are members of the Syndicate have kindly offered to classify them for shipment.

The Syndicate will also be glad to take charge of consignments with Garden marks from those who have contributed not less than 20 half-chests for bulking and to ship them for sale, charging 2½ per cent. commission proceeds exclusive of all Australian charges.

The requirements of the Australian Market, as far as can be ascertained are principally for the lower grades, and the Committee, therefore, recommend that the bulk of tea forwarded should consist of—

1. Broken Souchongs, or Broken Pekoe Souchong.—Black *leafy* with strong, dark, full-flavoured liquor.

N. B.—Dusty Broken to be particulary avoided.

2. Souchongs and Pekoe Souchongs.—Small even made leaf of good appearance, with clean, dark liquor.

The above two classes should form the bulk of the Consignment, but a small quantity of the following will probably find a ready sale, *viz*:—

3. Pekoe.—A Good medium Pekoe leaf with some tip.

Fair strength and brisk flavor Darjeeling Pekoes and Pekoe Souchongs, and also Souchongs, if not too bold, with good quality and flavor would probably sell well, but no *extra fine* Teas should be sent. Nothing worth over about 14 annas, and this should only form about a quarter of the consignment.

Packing.—The packages should be as uniform as possible in size, strongly nailed, *but not ironhooped.*

The size of the box should be 25" × 17" × 12", inside measurement, 45 lb. to be packed in each package.

The boxes should be neatly made, and Tares as even as possible.

Marking.—The only mark required is the garden mark, to distinguish the boxes on arrival in Calcutta, and "Tea Syndicate" on the opposite side.

Invoice.—To accompany each parcel.

COFFEE.

A FEW FACTS ABOUT COFFEE.

THE present depressed state of the coffee trade naturally turns the thoughts of all connected with it, to the general position of the article and leads them to ask the questions, are prices too high or too low? Is consumption larger than production or otherwise? There may be added, another, are outside influences at work determining the course of prices at the present time?

We have before us a large array of figures extending over a number of years, made up on one principle and therefore if not absolutely correct as to totals, at any rate perfectly trust worthy as representing relative quantities.

We find the landings in the six principal ports of Europe, and in an equal number of those in the United States, were in the under-noted years, as follows:—

	European Ports.	American Ports.	Total.
1879 landings	336,750 tons	190,970 tons	527,720 tons
8 „	298,700 „	141,816 „	440,516 „
7 „	314,700 „	145,568 „	460,268 „
6 „	282,150 „	110,748 „	392,898 „
5 „	330,050 „	153,131 „	483,181 „
4 „	263,400 „	118,469 „	381,869 „
3 „	285,450 „	112,157 „	397,607 „

The deliveries at the same ports for the like periods were as under:—

deliveries	tons.	tons.	tons.
1379 „	333,050 „	179,834 „	512,884 „
8 „	315,350 „	143,906 „	459,256 „
7 „	282,950 „	134,735 „	417,685 „
6 „	321,900 „	128,960 „	450,860 „
5 „	292,200 „	135,114 „	427,314 „
4 „	259,000 „	121,108 „	380,108 „
3 „	280,550 „	116,293 „	396,843 „

From the above figures it will be seen that 1875 was the year of heaviest landings, and 1876 that of the largest deliveries, until the year 1879 when both these sets of figures were exceeded.

With reference to the deliveries of 1879 it must be borne in mind, that in the latter part of the year speculative demand increased them, especially in the United States, far beyond actual requirements, and smaller deliveries in 1880 will most certainly have to be expected. But even when this is granted, the steady increase in consumption is clearly shewn by the above figures and still more so if we compare the totals of two years' deliveries, viz:—

1878-79	1876-77	1874-75	1872-73	
972,140	868,546	807,422	759,459	Tons.

Arrivals during the same periods were—

1878-79	1876-77	1874-75	1872-73
968,236	853,161	865,050	734,942 Tons.

and we cannot help being struck with the even progress which production and consumption seem to make. A consideration of these different statistics brings us to the conclusion that, in any case, we should not take extreme views as to the figures coffee may reach or decline to. There is no reason for particularly high prices because production is ample and likely to continue so, as it pays, whatever may be said of the labour difficulty in Brazil, and there is no reason either to fear an exceptionally low range of prices, because consumption has proved strong enough to absorb the largest quantities ever brought forward.

There will always be times of comparative scarcity or superabundance, but small fluctuations in price will easily allow the trade to tide them over. The heavy fluctuations, however, which we have had to witness of late, are the result of speculative elements which have been introduced to no profit for the speculators themselves but certainly to the detriment of all sound trading. The fall during last summer was too heavy, and there was nothing more natural than that prices should go up to a certain extent, and a very good and steady business might have been done at a gradual rise of 10s. or so. But no! Mincing-lane was to be turned into a stock exchange, and if we are well informed, the buyers of coffee at the very highest prices, were to be found amongst people who had no connection with the trade whatever.

Is it to be wondered at that such influences force the article entirely out of its groove, and can we wonder now at the sudden collapse of prices which means heavy losses and a great disturbance of trade? We are not informed on this particular point, but we shall be astonished if the last fall was not to a certain extent the consequence of speculators losing courage and forcing their purchases off with no more reason than that with which they were made!

The production of coffee in general as well as the trade therein, might be sound and safe, but for the disturbing influence of speculation. Many a planter would have secured a good price for his crop, and every one of them would have a fair idea of the time at which he ought to dispose of it, if those unaccountable oscillations in prices had not defied all reasoning.

Let us hope that the severe lesson taught this time will keep from the coffee trade, for some time anyhow, people who desire to make money without working for it, and who interfere with those who wish to work and are satisfied with a fair remuneration.—*Ceylon Times.*

MINERAL POISON AS A CURE FOR COFFEE GRUB.

AN experienced planter and visiting agent writes to the *Ceylon Observer*:—"I would ask you to bring before the public the advisability of using arsenic or other mineral poison for grub in coffee. A few years ago, when I was in America, the Colorado beetle had destroyed the potato crop over an enormous extent of country stretching from the base of the Rocky Mountains to the Atlantic seaboard, the damage done by the larva of a beetle almost indentical with the common cockchafer which is doing the mischief here. The beetle had two yellow stripes on one wing and three on the other if I recollect rightly, and at certain seasons they appeared in such enormous numbers that the streets in the town were covered with them in the morning, but the difference between the Colorado beetle and the Ceylon grub is very great, inasmuch as the Colorado beetle laid its eggs in the ground and when hatched they came out on the leaves and stems of the plants and literally ate up, first the potatoes and then the tomatoes over hundreds of square miles. The Ceylon beetle is different in so far that the larvæ remain and work entirely underground, and live on the roots of the tree. I may mention that I have seen hundreds and thousands of healthy young trees completely eaten underground by grub, and have dug up a tree otherwise healthy and got a grub with his mandibles in the bark of the root.

The Colorado beetle has in America been completely stamped out by the use of "Paris green," a very simple and inexpensive preparation of arsenic. It was applied to the potato plant mixed with two or three times its bulk of plaster of Paris not calcined but ground to an impalpable powder; the mixture was simply dusted over the potato leaves, and the arsenic was washed into the ground, and all insect life was destroyed. A long discussion was carried on in the Canadian and American papers and in several scientific journals both in America and England as to whether the arsenic was not taken up into the plant, rendering the produce of the plant dangerous for food, but it was clearly proved that no danger arose in that way. On the other hand, the preparation must be used with care in the application, or it will be absorbed into the system by handling the fine particles. Arsenic has been long used for rust and smut in wheat and also for the destruction of insects of various kinds, and I feel sure that a mixture of lime and Paris green forked into the soil would be of the greatest benefit to coffee estates infected with grub and insect pests, of which there are many. There is another preparation largely used: it is cheaper than Paris green and said to be equally effectual—"London purple," but I have never used it myself. I send you extracts from a Canadian paper which you may consider worth reprinting. I am fully convinced that grub in certain soils and in certain localities is doing even more injury to coffee than leaf disease, and frequently it is the combination of the two (can they be allied?) which causes the crop to drop prematurely from the trees.

SUCCESS OF LIBERIAN COFFEE IN CEYLON.

QUITE a representative party were able to accept an invitation from Mr. Forbes Laurie to visit "Liberia" plantation, 2½ miles beyond Rolgahawela, on the left hand side of the railway line. The shade trees under which the coffee and cacao were originally grown, (from the belief, now proved to be erroneous that shade of some sort was necessary for the healthy growth of this species of coffee) having been now removed, the estate can be seen, by those on the watch for it, from the passing trains. Even the brief glance thus obtained reveals the essentially different character of the gigantic coffee of the west coast of Africa to that of the so-called Arabian species which really owes its origin to Abyssinia, whence it made its way to Yemen, and from Arabia Felix to Ceylon and Southern India, accompanying the Mahomedan voyagers to Serendib and India, no-

doubt. However, this may be, there can be no question as to the recent introduction *to*, any more than the marvellous success *in*, Ceylon of the gigantic coffee of West Africa. The glance of "Liberia" plantation obtained from the railway shews at once the distinctive character of foliage and habit of growth of the Liberian plant, but it requires a visit such as was paid to the place on Saturday, to reveal the wonderful wealth of magnificent blossom and of big fig-like fruits with which the bushes, or rather trees, are loaded. Mr. Laurie's main object in desiring the presence of visitors was that they should witness the phenomenon of dense clusters of blossom on the very same wood and even the identical nodes which had borne a crop of fruit in the previous year. This is a departure and a most important one from the habit of the "Arabian" bush, from which "*wood*" which has borne a crop of fruit has to be pruned away. For an appreciable period, however, after entering the fifteen-acre field of the oldest coffee (and it is only three years old, if quite that) attention to this detail became impossible from the admiration excited by the truly gorgeous display of large snow-white blossoms, contrasted with the immense dark-green jack-like leaves. All agreed that for bridal occasions a branch of Mr. Laurie's coffee in full blossom would leave the traditional wreath of orange blossom nowhere. The rain, which had fallen copiously the previous day, had added a fresh feature of beauty to the scene by loosening numbers of the big blossoms, which, retained by the double-headed pistils, looked, for all the world like prehensile lillies. From the same cause, the rain, the ground under many of the trees was thickly carpeted with the white star-like blossoms, which gave forth as handfuls of them were gathered, the most exquisite jasmine perfume. But a Liberian coffee tree in full blossom, or loaded with fruit as well as blossom, must be seen to be appreciated. It is impossible for language adequately to describe what is essentially "a thing of beauty." As the serpent entered Eden, so the leaf fungus has found its way to Libreia, but the affected trees are as yet few and far between, and grub on this property is still unknown, though we heard of its ravages on one nearer Kurunegala. "Where the carcase is, thither will the eagles be gathered together," but one of the grand advantages of the new coffee is that its large-surfaced foliage enables it to bear, if not to resist the fungus. The tree is not denuded of leaves as in the case of the ordinary coffee." The general feeling found expression in the words "Well! whatever the fate of the old cultivation may be, there can be no doubt of the importance to Ceylon of the new coffee. Not that any one present despaired of the old favourite. On this the first plantation of Liberian coffee opened in Ceylon there are, we learned, 110 acres planted, nine feet apart (some cacao being interspersed) of which fifteen acres have commenced the full bearing stage. The view of the whole place and especially of the older coffee (still so young) from the bungalow where Mr. Laurie hospitably entertained his guests, was very striking, as well as the view from the estate, which is more undulating and contains more elevated ground than would be supposed after merely a passing glance from the railway. The party of Saturday were fortunate in the weather, which was cloudy, Dr. Trimen, the new Director of our Royal Botanical Gardens, repeatedly expressing the extreme gratification he felt. All the way up, indeed, the well-trained botanist was delighted to see growing in tropical luxuriance numerous trees and plants, which he had previously known only through the medium of cabinet specimens. A local amateur botanist, who has evidently formed an intimate acquaintance with our flora, was indefatigable in attracting Dr. Trimen's attention to the most striking individuals in the rich and varied vegetation, from rice in every stage of emerald green leaf to the full ripe corn, up to the grand talipot palms. This gentleman states :—" The show of blossoms on the Liberian coffee plants was quite a floral sight, apart from the fact that the same parts of the branches producing them are now or lately have been loaded with fruit. In many cases the ground was white with the flowers that had just fallen, whilst the plants were at the same time covered with newly blown flowers, and a large number which had separated from the young fruits, but which were caught by the bifid style and hung in masses along the branches."

The same authority has thus recorded his opinion of the soil of "Liberia":—

"The soil of Liberia estate is composed chiefly of the usual light-coloured cabook of the Western Province, and looks anything but a good soil for coffee, but then it has not been chenaed for 100 years at least, and during this period, or a much longer one, it has been covered by forest trees, whose roots have loosened the soil, whilst the fallen leaves have no doubt added to its fertility. In respect to the want of stones, it contrasts in a remarkable degree with the group of Liberian coffee estates opened on the bank of the Kaluganga, near Kalutara, most of which are very largely composed of gneiss rock, the coffee plants occupying the spaces containing soil amongst the rocks. Many of the plants on Liberia are rather tall and lanky, and some are a little topsided from the fact that they were left under shade for some time, but there can be no doubt that in a very short time all these will become fine well-shaped trees, now that the shade has been removed. With an ordinary fall of rain the climate is no doubt a good one for Liberian coffee, but until a large mass of the dense vegetation is cleared, it is feared the climate will be a feverish one."

All enjoyed their trip, and were pleased and deeply interested with what they saw, heartily wishing Mr. Laurie, a higher degree of success than usually falls to the lot of pioneers.—*Ceylon Observer*, February 23.

CINCHONA.

CINCHONA.—The following are the latest official statistics as to the culture of cinchona in the several Government plantations in India for 1879. Total number of plants, cuttings, and seedlings, in the Sikkim plantations, 4,881,055, on 2,174 acres of land; of these, the bulk, 4,260,000, are of *C. succirubra*, 421,500 of *C. Calisaya*, and 149,498 of *C. Ignota*. On the Thandoungyee plantation, Burmah, about 147,000 plants; on the Kalhatti plantations, Mysore, 36,055 plants; and on the Neilgherry plantations 1,043,101 plants, on 847 acres. There are also about 200,000 plants on private estates. The produce of bark in the year from these is stated at 377,000 lb.

IT appears to us that in addition to the undoubted success which has been arrived at by the Government in providing a very cheap and a very reliable antidote to one of the most destructive Indian diseases—malarial fever—in the shape of cinchona alkaloid, the low price of which places it within reach of even the poorest ryot in the country, there is more than a probability of the Government plantations at Rungbee being able in time to supply all the quinine required for medicinal use in this country. Mr. Gammie, the practical head of the Government Cinchona operations in this district, has recently been engaged in manufacturing sulphate of quinine from cinchona bark, gathered on the Government plantations. Judging from a sample of the result of his operations which, entirely without Mr. Gammie's knowledge, came into our hands, we have no hesitation in saying that the sample of sulphate of quinine manufactured in the Government gardens, which we had the pleasure of examining, answers all the tests as to its purity required by the British Pharmacopœia and in appearance is superior to the quinine manufactured by Pelletier, the great Belgian firm, while it is somewhat inferior to the outturn of Messrs. Howard. The quinine manufactured at Rungbee appears to be a very superior commercial article, and it will probably be found when the alkaloid can be produced in considerable quantities, that India will be entirely self-dependent as regards thoroughly reliable antiperiodic medicines, the price of which need not place them beyond the reach of even the poorest native of the country.—*Darjeeling News.*

SERICULTURE.

SERICULTURAL PROSPECTS.

IN reference to the mild and almost spring-like weather which has recently prevailed in the south of France, the *Journal de l'Agriculture* points out that its continuance will render it a matter of great difficulty to prevent the premature hatching of silkworm eggs in those districts. It would be advisable, therefore, at once to store them in very cold cellars, inaccessible to the outside warmth; or in default of such storage, to send them away into the mountainous districts where the cold lasts up to March or April. If this cannot be managed, the eggs should be kept in ice-boxes, under due precautions to avoid any excess of damp. Now-a-days, continues our contemporary, everybody is aware that the eggs require air, and that consequently they must be kept in very shallow layers in well-ventilated places. This precaution is rarely omitted at the periods when their respiratory activity is most marked, that is to say, for the first few days after they are laid, and during the period of incubation, but it is often lost sight of during the winter months, or is purposely neglected for fear of weakening the eggs. It would appear from some recent experiments by M. Verson, of Padua, that even in the cold season there is an active interchange of gases between the egg and the surrounding atmospheric or gaseous medium. Thus, eggs exposed for four or five days in October to an atmosphere of carbonic acid, hydrogen, or oxygen at a temperature of 5 degrees R., and then stored in the usual manner, were found to turn out very infertile at hatching time, thus showing that they had suffered much from the treatment in question. Some of the most practised silk-worm rearers are convinced that, to obtain good results, it is absolutely necessary that the eggs in store should be turned over gently at least once a week, so that they may be thoroughly well aired on all sides. But their management differs so much in different hands, that the whole business seems to be conducted by routine rather than with any true scientific knowledge as a guide.

TOBACCO.

THE experiments made with the growing and curing of Lunka and Madura tobacco at the Saidapet Experimental Farm during 1878-79 were very favourable, as also were those with an Italian variety, but the most successful of all was the Maryland tobacco which yielded the largest return and finest leaf. Nothing, however, is said of the market value of the different kinds experimented on. In a paper, entitled "Our Food Supply," the greater portion of which was laid before the Famine Commission, Mr. Benson, M.R.A.C., Acting Superintendent of Government Farms, Madras, says that the consumption of food in that presidency is probably not much less than 1·4 lb. a head per diem, the population of the Government lands, that is of all the country excepting the zemindaries, being about twenty-four millions. The amount of seed used per acre of arable land and sown with food-grains is probably not less than 56 lb., or ·5 cwt, thus causing a demand on the Government lands of ten millions cwts. The annual exports and imports nearly balance each other, so that the total demand from the soil for the support of the population is about 130 million cwts. In the lands belonging to Government there are annually about five million acres under irrigated paddy, thirteen million acres under unirrigated cereals, and two million acres under pulses. Mr. Benson says it is a common mistake to suppose that India, or at least Southern India supports a teeming population, or a population even in numbers alone in excess of that supported in some European countries. In only one district of the Madras Presidency (Tanjore) is the population per square mile of Belgium exceeded, whilst in thirteen it does not reach that of Italy.

WITH THE LAST NUMBER OF

THE INDIAN TEA GAZETTE,

OF WEDNESDAY, MAY 19th,

WAS COMMENCED A SERIAL STORY OF MUCH INTEREST AND INSTRUCTION

TO TEA PLANTERS.

ENTITLED

JACK RAYNSFORD—Planter,

A Story (Founded on Fact)

ILLUSTRATING

The Life, Experiences, and Adventures of a Tea Planter.

The Story will be continued throughout Volume VII., and will be separately paged from the rest of the *Tea Gazette*, so as to permit of being afterwards bound up by itself.

The Work has been written by a TEA PLANTER of great experience, and will, it is believed, afford equal instruction with recreative reading. It deals, also, with the incidents and occasion of the late Naga Raid, and other Historical Record connected with Tea in India.

The Work is copyright, and can only be obtained by present or future Subscribers to the *Tea Gazette*.

Volume VII. (No. 73 of the Series) of the *Tea Gazette* commences with the No. of June the 2nd, but new Subscribers to that Volume will receive the first instalment of the Tale, published with the May 19 No.

The Half-yearly advance Subscription to the Indian Tea Gazette is Rs. 9.

10, HARE-STREET, CALCUTTA.

NOTICE TO CORRESPONDENTS.

Our Correspondents and Contributors will greatly oblige us if they will take the trouble, where the returns of cultivation are stated by them in Indian weights and measures, to give their English equivalents, either in the text, in parenthesis, or in a foot-note. The bigah *in particular varies so much in the different Provinces, that it is absolutely necessary to give the English value of it in all cases. It would be a great reform if the Government itself followed the same course in all the official reports published by it.*

CORRESPONDENCE.

CINCHONA LEAVES.

TO THE EDITOR.

SIR,—I shall feel obliged if you or any of your readers can tell me if cinchona leaves are put to any use ? Would cinchona tea—made from the young shoots—be of any value as a febrifuge, and has it been tried ?

I hear that the bark from the roots of the cinchona tree is of much greater value than that from the stem ? Is it so, and of how much more value per lb.

DON D'EGLANTINE.

BURMAH PADDY BASKETS.

TO THE EDITOR.

SIR,—Will you be so kind as to inform me what quantity, precisely, is referred to as "a basket" of paddy in articles on rice cultivation in Burmah.

M.

NOTE.—The basket being a measure of capacity, it is impossible to give an exact weight, but from information received through one of the first mercantile houses in Calcutta, we believe a basket of rice throughout all Burmah, including British Burmah, weighs 16 tubbies. A tubby is equal to 1¾ seer ; one basket will therefore contain about 28 seers, a little over half a cwt.—ED., *I. A.*

THE GROUND NUT AND AFRICAN PALM.

TO THE EDITOR.

SIR,— Can you tell me how close ground nuts should be planted and whether the seed should first be raised in a nursery or planted at stake at once. Also, I would be glad to know what would be the probable yield of oil per acre from African palms planted hundred to the acre.

AFRICA.

SINDOOLA, CEYLON,
14th May 1880.

INFORMATION WANTED.

TO THE EDITOR.

SIR,—Can you tell me, if the dye from the *Arnotta* bush is valuable, and give me any information as to the manner in which the seeds should be cured ?

I shall also feel obliged by your telling me, where to procure cocoa (*Theobroma cacoa*) seed, and, where to apply for a good practical treatise on its cultivation, &c.

DON D'EGLANTINE.

THE MANGO.

TO THE EDITOR.

SIR,—In your issue of the 1st instant, there is a description of a method of improving the size of mangoes by notching the bark on two rings, I should be much obliged, if you or any of your correspondents could tell me, (*a*), whether the improvement in size is at the expense of flavour, (*b*), whether on an old tree, the same principle might be adopted on the upper branches, above the first or second fork.

STEPHEN HONLEY.

QUILON,
17th May 1880.

WOOD ASHES.

TO THE EDITOR.

SIR,—Can any of your readers tell me, whether the ashes of wood that has been burnt as engine fuel, are chemically different from the ashes of wood burnt on the open air, or on ordinary native hearths. It has been stated by a proprietor of a cocoanut plantation that the engine ashes kill the trees, but that the other ashes do not. I cannot but believe that this must be a mistake.

STEPHEN HONLEY.

QUILON,
17th May 1880.

CHARCOAL *vs.* HEATED AIR.

TO THE EDITOR.

SIR,—I am glad to see you have taken up the matter of "Charcoal *vs.* Heated Air." The manner in which it has been discussed so far, has led to no definite result. I think, both your plan and that recommended by Mr. Schrottky (with whose views in this matter I entirely concur) should receive immediate attention, as, only by some such trial can this matter be definitely solved. It is to the interest of all to look to it at once, and use their best endeavours in every way to remove the Indian tea out of its present "slough of despond."

By-the-bye, why do managers make so many different teas? Surely it much enhances manufacture charges? Why not keep to three good uniform teas?

1. Pekoe, 2 Pekoe Souchong, 3 Broken Mixed, the last, a mixture of all brokens; (large leaf to be forced through a No. 8 sieve, always taking care to see that the proportion mixed of each be the same). My own opinion is, that by following this method, much expense would be saved, the teas would find a better market, and the brokers would not complain of one "break" of tea being so much inferior or superior, than another, careful packing also tells—I would recommend half chests (40lb. for the Pekoe, and full chests for the other teas, and also that the *proper* quantity be packed into each, no more and no less.

I am much pleased to find that there is every chance of Indian tea getting into the Australian market. The Indian tea exhibits have won high praise out there. The colonists are great tea drinkers, and, no doubt, when they come to compare our Indian teas with the *trash* they have hitherto got from the China merchants, they will throw over the latter in our favour. Care must be taken not to pour too much Indian tea into the Australian market at first. They must have time to acquire the taste of the new tea, and, when once India gets that market, it is to be hoped managers will do their utmost to keep their teas up to the mark, and, not by *any* chance send out a pound of bad tea, and always see that their teas are carefully and properly packed and classed.

DON D'EGLANTINE.

BAMBOO PAPER STOCK.

TO THE EDITOR.

SIR,—A correspondent referring to my letters inserted in your journal, informs me, alluding to the *cutting of bamboo*, that in the year 1875 he took charge of a tea plantation which he found in bad condition, among other deficiencies there being no houses for coolies, and he says, finding a tope of bamboos full grown, he cut down the *whole* of the stems within 6 inches of the ground to utilise them for building, and gave the said tope no more care or concern. In 1877, when he left the garden, the same bamboo was in the same full growth, as when he cut it down, the stems being fully thirty feet high, and in a fit condition for being again used for similar purposes. Now this is by no means an isolated fact, as I have similar information sent me from other districts both in the East and West Indies. At the same time I am disposed to think that such unsparing treatment, as cutting down the whole stem growth, would result in the deterioration of future growth; and I think that only a portion, say ⅔ of the stems, should be cut at each cropping, and those, cut some 4 feet from the ground. The stumps and stems thus left would then fully maintain the vegetative functions of the parent stool, and if, after such cropping or cutting, nourishment, especially in a dry season, could be given by irrigation, reproductive growth would be facilitated.

We, so to speak force dame nature both in animal as well as vegetable growth; and, pursuing the same system with bamboos, I fail to see why the same result should not follow. In Peru, in Spain, in Egypt—each of which countries produces a large tonnage of sugar—*water*, irrigation in fact, is invariably pursued. In other countries indeed, a productive crop is almost entirely dependent on the rainfall, and every one conversant with the growth of bamboo knows that it flourishes best in a humid climate.

Heat and water *both* seem necessary for bamboo growth. Heat in Southern India is continuous, but water only during monsoons, when bamboo pushes growth. Assure the water by irrigation, as and when required, and you will, I think, assure continuous or nearly continuous growth.

My correspondent does not mention the variety of bamboo he cut down from its height. I imagine it to have been the common *Bambura Tulda*, possibly *Bamb. Arundinacea*, from the height of stems 30ft. The locality, however, the Dehra Doon, N.-W. P., and at an elevation, of from 2,000 to 2,500 feet, is not most favourable to bamboo growth.

In Burmah, I learn, from the good authority of residents, that many hedges and topes, cut very keenly, year after year, do not suffer, but reproduce continuously; but in Burmah and Tenasserim provinces, we have naturally most favorable conditions for the growth of bamboo, and I am assured that the nearer the water, the more prolific its production.

THOS. ROUTLEDGE.

Claxheugh, Sunderland, 19th May 1880.

CATTLE BOX MANURE.

TO THE EDITOR.

SIR,—With reference to your article headed Cattle Manure Experiment, in this month's issue, I think there is a slight inaccuracy in the description of the method of feeding cattle in the box or *hamel*, as it is called in Scotland.

The cattle are housed separately or in pairs in a box, or shed, sunk in the ground some 3 or 4 feet with masonry walls underground and well roofed in, so that no rain can penetrate; but cattle are put in to fatten for the market, and are not removed from the shed until fit to kill. The effect of constant treading on the litter, a thin layer of which is carefully and evenly spread night and morning, is that the manure is consolidated and compressed, so that it does not poach, and there is little or no escape of ammonia, and when the cattle are removed and the manure taken out, its value is greatly increased from the oil cake and other food given the beasts, and it cuts out like a cheese or solid substance instead of the fire, fanged stalky stuff, we usually get on a coffee estate. I am now building a cattle shed on my estate, a description of which will perhaps be useful to some of your readers as being cheap and containing the advantages of the box system.

On the side of a hill excavate a pit varying in size according to the number of cattle to be housed. They should be confined as closely as possible, so that the litter may be thoroughly trodden. This pit will be, say 3 feet deep on the lower side, and 6 feet on the upper, and in the middle of the lower side there will be an opening, say 3 feet 6 inches wide, cut out to the level of the bottom of the pit. This will be the door or entrance to the cattle shed, and will be filled up with well rammed earth, as the manure fills up the pit. The walls of the shed to be formed of jungle-wood posts, placed close together, from 9 to 6 inches diameter, the ends of which are put in the ground to have the bark peeled off, charred some 4 feet, and to be *charred*, and tarred while hot. The roof to be thatched and the eaves to project well over, and a ditch to be cut on the upper side and two ends, to carry off the rain water. The walls to be built close inside the pit, and the cattle can be left in the shed day and night with perhaps a run out for two or three hours during the day for water, and fed and littered down night and morning. In the dry weather when grass and coolies are scarce the cattle can feed out in the day and be littered down at night only. In fact cattle in Wynaad will not thrive unless they have exercise during the day. When the shed is full, it can be left until the manure is wanted, the cattle being removed to a new shed which should be ready. Eighteen years ago I was engaged in getting out a book on farm buildings, so that I write with some confidence on this subject.

FREDERICK P. HUGHES.

Wynaad. 16th May 1880.

TRANSPLANTING TEA.

TO THE EDITOR.

SIR,—Have any of your tea-planter readers ever tried to plant long-rooted tea plants which have attained the age of three years in the nurseries, and whose roots have attained a length of some 14 or 15 inches? The mode of transplanting which I have adopted

PROPRIETOR—CHARLES GOULD.

THE SMITH AMERICAN ORGAN,

Wholly new designs and effective combinations in Reed Organs.

THE American Organ has been, and still is, the most popular and valued instrument for Churches and Chapels. Immense numbers of them are used in public worship, and it has been found that no other Reed Organs have so much sustaining power joined with such melodious quality of tone.

Style No. 10, *Seven Stops.*

This Style is furnished with two complete sets of reeds of five Octaves. Each set is divided and has a separate stop, for the upper and lower half. The upper half of the first set of reeds is named Flute, and the lower half Principal. In the second set the upper half is named Dulciana, and the lower Diapason. The first set is an Octave higher in pitch than the second, so that the instrument has practically a compass of six Octaves. By having the sets divided, it will be seen that more effect can be produced. The remaining stops are Tremolo, Diapason Forte, and Principal Forte. [*Net Cash, Rs.* 400.

Style No. 16, *Ten Stops.*

This instrument has two-and-a-half sets of reeds, and an Octave of Sub-bass. It has ten stops, *viz.*, Diapason, Dulciana, Flute, Principal Kulophon, Sub-bass, Tremolo, Principal Forte, Diapason Forte, and Octave Coupler. The last stop doubles the power of the Organ, and with the aid of the Sub-bass renders it a powerful and effective instrument for Churches and Halls; at the same time its power is not obtained at any sacrifice of delicacy, and it will be found a most desirable instrument for home use. [*Net Cash, Rs.* 650.

Style No. 20, *Nine Stops.*

This instrument has three complete sets of reeds. Two of the sets are like those in the preceding Styles, having the Principal and Forte Diapason and Dulciana stops. The third set is new and distinct in quality, the upper half is named "Aulodia" and the lower half "Fagotte." The tones of this set are unrivalled in clearness, smoothness, and tender beauty, and their effects in connection with the swell are surprising.

This Organ is one that will be approved by all persons of refined taste. [*Net Cash, Rs,* 750.

***N.B.*—The above prices are exclusive of packing charges.**

SELLERS' QUINQUININE

Entirely supersedes Quinine, at about one-third the price.

J. SELLERS, the inventor of the process for manufacturing this article, confidently recommends it for use in India and all districts where Quinine is employed.

It is the only reliable combination of the entire alkaloids of bark, and as a tonic and antiperiodic in the treatment of Ague Fevers, and Malarial diseases, it is superior to the Sulphate of Quinine.

It is used in several of our large Hospitals, and very extensively in private practice with the greatest satisfaction.

It resembles Quinine in appearance, and is given in the same doses as Quinine.

In an article on Cinchona and its alkaloids in the *British Medical Journal*, June 28th, 1879, the writer states:—" Sellers' Quinquinine and Howard's Quinine are equally good medicines. On this point I speak from careful observation, uninfluenced by chemical analysis, or by the statement of the vendors. Sellers' Quinquinine is similar in appearance to Howard's Quinine."

J. Sellers, the inventor and solemaker, cautions purchasers against worthless and spurious imitations which are being advertised. Every genuine package bears the label of J. Sellers, London. Sellers' Quinquinine should always be stated in orders.

Sold in 1 oz. bottles, 5s. 6d., and in 4 oz. bottles and 25 oz. tins at reduced rates.

SELLERS' MISTURA BISMUTHI COMP.,

(Registered), Stomachic and Anti-Dyspeptic, a perfect solution of Bismuth, miscible with water without precipitation, and is acknowledged to be the most useful, convenient, and efficacious preparation of Bismuth we possess; being often given with benefit when all other preparations of Bismuth have signally failed.

In cases of dyspepsia, pain after food, gastric irritation with sickness, nausea, especially due to pregnancy, and whenever there is general depression and lack of nervous energy, with loss of appetite or inability to assimilate the food, it is given with almost unfailing success. In those troublesome and difficult cases arising from sedentary habits, or excesses of any kind, so frequently met with in medical practice, it is a most reliable remedy. It is specially adapted for Indian medical practice and tropical districts.

208, Blackfriar's-road, London, S.E.
May 15th, 1879.

Dear Sir,—I have used your Mistura Bismuthi Comp. for the last ten years, and have always found it a most reliable and useful mixture —pleasant to take, uniform in strength, and keeps for any length of time without change. I can with much confidence recommend it to my brother practitioners, for in the *many thousands* of cases in which I have prescribed it, I can safely say that I have never met with one failure. I am sure the sale would be much greater if more generally known.

Yours very truly,
T. SANDERS WORBOYS, M. R. C. S., L. S. A.

To Mr. Sellers,

It is necessary to caution the profession against spurious imitations, which do not in the smallest degree represent this preparation. All orders should specify "Sellers' Mistura Bismuthi Comp.," which is protected under the Trade Marks Act.

Each Bottle contains the exact Formula on the Label, which is Copyright.

Sold in ½lb., 1lb., 2lb., and 5lb. bottles at 10s. per lb., by the Sole Maker and Originator.

JOHN SELLERS, Manufacturing Chemist, 17, FARRINGDON-ROAD, LONDON, E.C.
May be obtained through any Wholesale Druggist in the United Kingdom, India, and the Colonies.
Agents:—BOMBAY, CALCUTTA, MADRAS.

STEEL STEAM CANOES, STEAM GIGS, STEAM LAUNCHES, all of Steel throughout with patent 3 cylinder "Compound and High Pressure (combined) Expansive Engine," convertible from the latter into the former by the one Lever that solely controls its motion, having no dead-centre and *capable of instantaneous reversal* while running at the highest speed. Portable Folding Boats, Corrugated Iron Sheds with patent Pillars, Portable and Stationery 2 and 3 Cylinder Engine, and Road Locomotives. For full page illustrated advertisement, see February, March, and April numbers.

Light draught Steel Barges or Flats adapted for the carriage of Produce in Inland Waters, Creeks, Shallow Rivers and Canals with very powerful little "Tug Steamers" of light draught, and having four Propellers, or Paddles and twin Propellers. Seaworthy Launches, &c., &c.

E. I. R., Bengal.

in regard to such large plants is this:—Cut the roots, keeping only 4 or 5 inches, and heavily plaster them with nursery earth and then plant. This is how I now fill up the vacancies in my garden. I get the work done generally by female coolies. The result of such a planting is very satisfactory. The vacancies both in high and flat ground can be filled up by this mode. The plants I have made use of belong to the class of hybrids. From 9th April to 12th May last I planted 25,225 bushes with a force of labour consisting of 102 men, 441 women, and 132 children, which cost me only Rs. 124-11, and not a single plant was lost.

Is not this a very cheap and easy way of transplanting long-rooted plants? In comparison with the cost of what I planted from November 1879 to 9th April 1880, according to the ordinary mode, this new method has cost me only 15 per cent.

S. C. D.

Sylhet, May 23rd, 1880.

NOTE.—Our correspondent is quite correct. It is evidently a labour of great cost to move old seedlings entire, the tap-roots necessitating the digging of very deep pits, both for the removal of the seedling from the nursery and also as a new home for it in the garden. We tried this with some six-year old seedlings of common China variety, and the attempt was thoroughly successful. We have never personally tried it with hybrid plants, but we presume that what succeeds in the one case would succeed in the other.—ED. *I. A.*

CINCHONA TREE MEASUREMENTS.

(To the Editor of the Ceylon Observer.)

DEAR SIR,—I notice that a correspondent has sent you measurements of cinchonas, which considerably exceed those I gave you. As, however, he took his measurements some two months after I observed mine, I thought I would measure again; and such has been the influence of the fine growing weather we have had that I found the same tree to measure 4 ft. 7in.! This was measured in presence of a friend, and if I remember, is a little short of your correspondent's tree. Yet, bearing in mind that mine was an unpricked seedling with months of drought to endure, I think we may say "quits" about a competition in which it is so hard to judge exactly.—Yours truly,

J. F. W. GORE.

Mukeloya, Deltota, May 8, 1880.

RED BARK CINCHONA.

(To the Editor of the Madras Mail.)

DEAR SIR,—As all facts connected with cinchona cultivation in Ceylon are just now very interesting to many of your readers, I think it desirable to give publicity to an analysis of *Whyddon* cinchona succirubra bark furnished to me a few days ago by Mr. C. E. H. Symons. He writes thus:—The bark "contains total alkaloids 3·870 per cent. of which crystalized sulphate of quinine - 1·533 per cent, which would give a gross value in London market of 2*s*. 6*d*. sterling per lb., I may add that the proportions of cinchonidine and quinodine are very good, the percentage of cinchonine being small. I hope you will consider the result satisfactory."

The interest and value of the analysis arise from the fact that the trees from which the bark was cut (stem bark) were only 21 months old, having been planted in June 1878. They are grown in old and luxuriant coffee which I planted in 1856, and the particular field is at an elevation of nearly 4 000 feet. The trees at the time of cutting, had attained a height of between five and six feet.—I remain, dear Sir, yours faithfully,

JOHN NORTHMORE.

Colombo, 11th May 1880.

CINCHONA ANALYSIS, &c.

(To the Editor of the Ceylon Times.)

SIR,—As a good deal of inquiry is made about cinchona in all its growths and forms, it may prove of interest to your readers to have the following figures:—

800 trees 10 to 12 years old, on Choisy Estate, gave an average of 17lb. each, dry bark shipped. One tree, a sample of a dozen probably, measured 38 feet 6 inches in length; 3 feet 6 inches in girth; giving 138lb wet bark, and turned out 44lb when dry.

Colombo analysis gave—2,127lb. stem, and quill bark, 1,675 per cent. chrystallised sulphate of quinine, valued at 2/9 sterling gross in the London market,

1,847lb. root bark, contains 2·307 per cent. sulphate valued at 3/10

1,191lb. chips, contains 1·605 per cent. sulphate valued at 2/8.

There will be an average loss in weight over the whole parcel of 11 per cent. To get at the value f.o.b. in Colombo, deduct from gross value in London 11 per cent. drysge, London charges and allowances, Colombo charges, frieght, and exchange.

19th May 1880. E. W.

TEA AND ITS FUTURE IN CEYLON.

PRUNING, FLUSHING, AND PICKING.

(To the Editor of the Ceylon Observer.)

SIR,—This subject seems to be much disregarded in Ceylon. When we hear of the doleful cries from all sides of the coffee prospects being a toss-up for another season, it is best for us to turn and look about to our new industries and see what may be the future of the tea, which is now being greatly extended all over the Island, and will no doubt, with cinchona and cacao, be our leading enterprises. We have large acreages still unopened which will prove a source of competition to many, who have yet small capital remaining, in a few years' time; and it is for those who have had any practical experience to come forward and give every assistance to men wishing to invest their year's savings or remainings in these new openings. What is much wanted is men who can really afford such assistance. There are planters in the island who have through their own means gained a slight knowledge of tea planting, &c., but this slight knowledge is or will prove a source of danger to them hereafter, and instead of taking advice they may try to give it and lead others astray—though unintentionally. What I wish to draw the attention of tea-growers to, is the want of attention paid to the pruning, flushing, and picking, on which depends entirely the future of tea. There are no doubt different times and various styles of pruning in different parts of the island; but which have proved the right time and style? Here only experience can come forward and answer the question. Pruning in June or July are very good months, or soon after the bushes shew a decided tendency to cease flushing. Taking this for granted, the next point is what style of pruning will mostly benefit the yield? Some say a surface or flat one, others a round top cutting, and again a few advocate what is called the cup-shaped touch. I have seen all these tried, and largely too, but from my experience I would strongly push forward the last style; here we have not only the flushes confined within a given surface, but the heat of the surrounding out branches increases the growth and strengthens the flushes. I have noticed that in tea gardens in Ceylon, some have pruned their trees below to give the plants the appearance of a single stem or umbrella look. This is indeed a great fallacy and mistake. A very few gardens in Assam shew any acreage of this kind. Where Col. Money speaks of it is in the pure indigenous plant, little of which is really grown in India. The more a tea plant bushes from the ground, the larger will be the top surface, and consequently stronger of flushes. In parts of the Himalayas, such as Kumaon, Nynee Tal, Almora, &c., planters, to make a bush, put in three and four plants in each hole, and in no instance a single plant, and planters strongly advise you against it. What is meant by cup-shaped is cutting out the centre or heart of the bush to as far as you consider proper, but not in any way touching the outside or spreading laterals—when the flushes after pruning have attained a growth of 4 to 6 inches, the latter preferable, the first three leaves, and no more should be picked, giving and outturn in bulk of Pekoe Souchong, or if the estate is young, of Pekoe—the great fault with the picking here at this stage is, giving too much as a *neerick* or quantity for a day's work; where they, the pickers, over-pick these young tender shoots they destroy all the future crop and throw back the next flush. Three, and in no consideration more, leaves should at any time be picked. This will not only give you a full outturn of 400 to 400lb. of tea, but such teas as will find a ready market at home. I have been over several large estates in the Island, and I was very much surprised at the coarse leaf and the large quantity each person brought in.

C. A. R.

(Late of Assam.)

Dolosbage, 1st May 1880.

AGRICULTURE IN INDIA.

(To the Editor of Allen's Indian Mail.)

SIR,—Mr. Robertson, in the interesting paper on agriculture in Southern India, which he read in the Society of Arts room on Friday, raised several questions, the importance of which can scarcely be overstated. India is

essentially an agricultural country; the bulk of her population subsists by tillage, and her revenue is derived chiefly from land. Everything, therefore that hinders the development of agriculture vitally affects the interests of the Government, as well as those of the people; and among the causes indicated by Mr. Robertson as operating in the direction the assessment of the land revenue is, perhaps, the most powerful.

Over the greater portion of the Madras Presidency the assessment of the land tax is, under the existing system, annually liable to enhancement at the option of the Government, and is actually enhanced wherever the productiveness of the land is found to have increased. The working of such a system necessitates the utmost caution lest the officers empowerd periodically to re-adjust the land tax should so increase it as to leave too small a margin for the support of the cultivators, or to absorb the profits due to the expenditure of capital, and thereby discourage the application of capital to agriculture. During the last thirty years several causes have been at work, which afforded the greatest encouragement to agriculture in India. The construction of Indian railways with English capital not only opened new marts for Indian cultivators, but, by raising the price of labour and ameliorating the condition of the labouring classes, led to a larger consumption of agricultural produce. The Crimean War, moreover, by closing Russian ports, created an additional demand for Indian seeds and corn, and the Civil War in America gave an extraordinary impetus to the cultivation of Indian corn, jute, and other articles of Indian produce. These circumstances resulted in a rapid extension of cultivation throughout India, and the Chairman of the meeting at the Society's-room demonstrated, by statistical figures obtained at the India Office, the great increase in the area under tillage which occurred in the Madras Presidency during the period above mentioned. The authorities in India failed, however, to take into account the temporary nature of several of the causes which had led to this prosperity, and their belief that the cultivators in their improved condition, could bear much heavier burdens than previously, induced them to effect excessive enhancements in the demand upon land, amounting in some instances in the Bombay Presidency, where the revisions had not taken place for many years, to 100 per cent. of the existing tax, and, in some cases, to a greater proportion still. The restoration of peace in Europe and America, meanwhile, had brought down the price of Indian agricultural produce nearer to its former level, and the proceeds of the crops in India no longer enable the cultivator to satisfy the enhanced demand of the Government. In his altered circumstances the ryot, in order to protect his field from attachment for arrears of revenue, had recourse first to the savings laid by in the years of prosperity, and, when these were exhausted, to the assistance of the money-lender, by means of a mortgage of his farm. With a continuation, however, of moderate prices, and with interest accruing on his debts, the ryot was ultimately, in numerous instances, unable to meet his increased liabilities, and his farm was put up for sale by the revenue authorities, subject to the enhanced rate of land tax, but free from the claim of the mortgagee, who thus lost the money he had advanced. Notwithstanding the last-named condition, which was favourable to buyers, many of the farms met with no purchasers at all, and thousands of acres of arable land especially in the Bombay Presidency, were thus annually thrown out of cultivation between the years 1869 and 1876. The drought in the latter year found therefore the agricultural population in Madras and Bombay in greatly reduced circumstances; and when the crops in the following year likewise suffered from want of rain, many millions of human beings died of starvation or disease caused by insufficient food, and many millions sterling were lost to the State through deficient land revenue and famine relief expenditure. The immediate cause of all this misery to the people and of this heavy loss to the State was the impoverished and almost destitute condition in which the drought of 1876 found the peasantry and the landholders in general. Such destitution, however, would obviously not have occurred, looking at the remarkable prosperity which the same classes enjoyed at the close of the American war, had they been allowed to retain the savings effected under the prosperous circumstances of preceding years, and to continue applying them, as many had already done, to the sinking of irrigation wells and to other improvements in their farms. The primary cause of the evil must consequently be looked for in the excessive enhancement of the land tax in Bombay, between 1869 and 1874, and in the maintenance of unduly oppressive rates in Madras, where the land tax is intentionally fixed at so high a figure that it is recoverable only after full crops and leaves outstanding balances in other years, thus keeping the bulk of the cultivators in a permanent state of poverty and indebtedness. I am glad to observe in the report of the meeting a confirmation of the views expressed above, in the following sentence of Sir William Robinson's speech on the occasion;—"The land tax in India is a very heavy fiscal demand amounting to one-half the rate produce of the land, a proportion which in England would go a long way to arrest improvement." Mr. Robertson thought that remedy would be found in the permanent limitation of the Government's demand on land, as it would induce the application of capital to agriculture; and Sir Charles Trevelyan probably entertained the same thought when he said, on the same occasion, that "the burdens of taxation could be lightened by greater certainty."—I am, Sir, your obedient servant,

J. DACOSTA.

Devonshire Club, May 10.

The Indian Agriculturist.

CALCUTTA, JULY 1st, 1880.

CANAL IRRIGATION.

ONE of the most noteworthy articles in the first monthly issue of the London *Statesman* is entitled "Irrigation in Upper India," and if we must accept its conclusions the prospect which it sets before us is appalling. The views expressed are not novel. Similar views were long ago stated in the *Agriculturist.* They have forced themselves on many observers of the effects of irrigation in Northern India, and have been set forth at length by Lieutenant-Colonel Corbett in his "Climate and Resources of Upper India," the book which supplies the basis of the article to which we refer. The subject is one on which we do not wish to dogmatise. But it calls urgently for discussion and inquiry. If Colonel Corbett's views are accurate, then we must open our eyes to the alarming fact that we are steadily and hopelessly ruining those vast tracts of Upper India which we have believed ourselves to be enriching by our systems of irrigation. The only question is, how long it will be before Upper India becomes a lifeless desert of salt. We are all familiar with the fact that in former times there were fine canals in the country which we found fallen into disuse and ruin, when we became masters of India, and we take great credit to ourselves for digging them again, and pouring afresh the waters of irrigation over plains that without them would often be parched and barren. It is now suggested that perhaps the rulers who allowed these great works to fall into neglect and decay, were not careless of the country's good, but had learned, as we are learning now, that the canals were the mightiest of defertilizing agents; and that the people ceased to use the water simply to save the land from utter barrenness. Whether or not this was so, the facts now alleged as to the production of *reh* by the continuous use of canal water are grave enough to startle the most ardent believer in irrigation, and to make him examine the foundations of his faith.

Apart from and prior to the production of *reh,* the mere hardening, baking effect that follows copious irrigation is doubtless an evil. The "surface soil is brought into the position of sun-dried bricks; the more water that has been applied to the land, the harder the soil becomes; and while its powers of absorption and radiation are reduced, those of reflection and retention of heat are increased; and we also find that the power of capillary attraction possessed by the land is increased, and that the soil so compacted will sooner become dried up than soil left loose and open." Canal irrigation—if the above may be accepted as a faithful description of its effects—can, clearly, be entirely beneficial only when it is accompanied by a style of agriculture very different from what obtains in India and from the best that we can hope to introduce. Deep ploughing ought to go hand in hand with canal works. Deep ploughing and sub-soil drainage would, we believe, effectually remedy the baking of the soil and also prevent the efflorescence of *reh.* But we have only to observe the ryot and his bullock to admit that before we can look for the introduction of deep ploughing, the *reh* will have done its work, and it will then be a question of reclaiming a parched and saline desert. So far back as 1850, the growth of *reh* was thus described by the Superintendent of the Western Jumna Canal:—

> "A white efflorescence has made and is making its appearance in various places, destroying all vegetation, with which it comes in contact. The barren space gradually increases in area, and speedily the ground thus affected is deserted by the cultivators, who forthwith assail the civil officers with petitions for remission of revenue."

The ruin has, it is said, been steadily progressing since 1850, and in 1874 a canal officer writes :—

"Canal water creates *reh*, especially when it runs above the surface of the ground-level. It is with canal water that the disease is propagated. The canal, in its passage through *oosar* lands, drains off the saline matter in the *oosar*, and deposits it elsewhere. Three to seven years is the time required to poison the land, and the *reh* to show itself. . . . No physical law governs the character of the land in which the *reh* appears. It is only necessary to irrigate good land with poisoned water for four or five years to propagate *reh*.

The writer in the London *Statesman* gives a brief history of the growth of *reh* in the tract watered by the Jumna canal. After the system had been re-opened by the British authorities, there was a rapid extension of cultivation, and new crops, such as wheat, cotton, and sugar-cane, began to be grown. But in 1850 the Collector of Paniput reported that the lands of thirteen villages in his district had been seriously injured by the saline efflorescence which then began to be regarded as a calamity of a very threatening nature. Of the lands of one village, which were particularly examined, it was found that 21 per cent. had been made sterile. In 1856 it was found that one-tenth of all the villages in the Delhi territory had suffered in this way. After this, Mr. Sherer, a civil officer, was deputed to investigate the matter, and he reported that lands which formerly had been singularly rich, were now "barren and depopulated, and either covered with *reh* or hopelessly water-logged." "The spectacle," wrote Mr. Sherer, "of sick women and diseased children crouching among the ruins of their houses, of haggard cultivators wading in the swamps or watching their sickly crops, or attempting to pasture their bony cattle on the unwholesome grass, is present to my mind constantly." The prime cause of this misery he believed to be the "plague of water" and the consequent sickness, aided by the unrelenting system of taxation which regarded not the condition of the tax-payer. The Government were alarmed and began to cast about for a remedy. Colonel Baird Smith proposed to close the canal, which was supposed to be defective in construction, and to excavate a new one upon improved principles. But then came the mutiny, and the project dropped. The mutiny was followed by the famine of 1861, the beginning of a ghastly procession of these calamities. Every one saw the need of doing something, and it seemed to most men that the only remedy for drought must be irrigation. Irrigation might, indeed, have its own disadvantages, but these, it was thought could not be comparable to the terrible evils of extensive and frequent drought. In Lord Mayo's time it was proposed to borrow ninety millions sterling in order to cover India with a net-work of canals, and 7 per cent. on the cost of construction was to be the rate charged on the ryot whether he chose to use the water or not. "Had this scheme been carried out"—we quote the monthly *Statesman*—"the British Empire in India must have collapsed. The liveliest imagination cannot even dimly realise the extravagant achievements of the Indian Public Works Department, when in possession of a guarantee to the amount of seven per cent. on all they expended. The people would have perished of fever by thousands. Upper India would have been smitten with barrenness from one end to the other ; and the Government reduced to bankruptcy." In the meantime *reh* was steadily spreading itself over the land. In 1868 the surface of the country for miles on the left bank of the Jumna canal was "as white as snow," and where this was the case "not even grass" would grow. The climate had worsened, bad fevers prevailed, and in many villages "population was either at a standstill or was retrograding." Since then, it is said the curse has been "marching rapidly over the country." In 1878 Government appointed a committee to visit the worst *reh* districts, of which committee Mr. Medlicott was a member. This committee has reported, but its report has not been published, and the results of its investigation are not, therefore, available. Mr. Medlicott's opinions on the production of *reh* are, however, known, and—though it is somewhat long—we shall borrow the following extract :—

From motives of beneficence and of economy, the object of the department is to make the given supply of water in any canal cover as large a surface as possible. The cultivator (if the quantity supplied affects his water-rent) would have even more active motives to make his share go as far as possible, regulating his draught to just that amount which would keep the soil, to a small depth, in the state of moisture required for vegetation. Little, if any, thorough soaking, with underground escape, or even surface washings, occur on canal lands. The arrangements are made to retain the irrigation water in each field till drunk by it, and this acts for the rains also. A more ingenious system for the production of *reh* could scarcely be devised. It is true that the primary elements of *reh* are scanty, and very slowly set free on alluvial soil ; but then the canal water would daily bring its dose of ready-made *reh*. This goes on over a country where the rainfall ranges from less than 10 to less than 30 inches, where the mean humidity is under 60 per cent. of saturation, and the mean temperature 75°, with summer monthly (day and night) means over 90°. It may safely be said that over a large portion of this land not a drop of the fertilising water so distributed escapes. . . . . The area irrigated per cubic foot of discharge is about 200 acres ; and if this were being watered all day and all night all the year round, it would only get 3·6 feet of water. The irrigating season is about half the year, and not much work is done at night, except in the very high demand season, so that two feet may be taken as the very outside any irrigated field ever gets in the year.

It has, besides, to be noted that while in Upper India sweet water is found at a depth of from 60 to 100 feet, there is interposed between this and the surface an upper water-bed of a strongly saline character. The effect of canal irrigation is said to be to raise the level of the impure water-bed, to bring it within the reach of active evaporation, and thus to cause a profuse efflorescence of *reh* on the surface.

We have given but a very imperfect abstract of the article in our London contemporary, which we commend to the attention of our readers. And we do not wish to commit ourselves to any decided opinion on the important subject of which it treats. But it is a subject which calls loudly for discussion, and we shall welcome contributions to our knowledge of it from those who have had means of observation in the canal watered tracts of Northern India. The writer of the article evidently believes that these canals are slowly but surely converting the country into a desert, and he has no remedy to suggest. If we go on pouring canal water over the country, we shall, in process of time, bring on universal sterility ; if we close the canals, we must face the certain prospect of frequent famines from drought. The drought again, is in large measure the consequence of the process of forest denudation which, from different causes, has been going on more or less steadily for centuries, and with increasing celerity in these days of multiplying railways which devour the timber wherever they place their iron foot. Thus it would appear that the mightiest blessings which we introduce at enormous cost into India, have a fatal tendency to develop into desolating curses. We hope it may be found that the picture has been overdrawn—that the evil is less enormous and less invincible than it seems. But though we deprecate panic, we see ground for serious alarm, for the most painstaking investigation, and for cautious dealing with the facts that can be gathered from the experience of thirty years.

MINERAL OILS IN INDIA.

A VERY full and interesting report on mineral oils has recently been prepared under the orders of the Government of Bengal and submitted to the Municipal Commissioners of Calcutta. A special committee was appointed for the purpose, nearly twelve months ago, by the local Government, and much useful information has been collected by it on the subject. A brief review of some of the leading features of the report may not be out of place, as the matter is one which affects the public safety

and convenience in no small degree, not only in this city but throughout India. Under special enactment, Act III. (B.C.) of 1865, the importation, or rather storage, in Bengal, of inflammable oils, the flashing point of which is below 100° F., is to a certain extent placed under restrictions, but the law not being sufficiently stringent, it is practically inoperative and calls for early revision. In order to ascertain to what extent the requirements of the existing law are actually observed or evaded in this city, Mr. Pedler, on behalf of the petroleum committee, personally made some experiments. He procured as many as eleven samples of kerosine oil from various European and native firms in Calcutta, of which no less than nine samples, on being submitted to careful tests, were found to flash at between 85° and 90° F. On this point the Committee very appositely remark that "with oil of so low a class freely procurable, it is perhaps remarkable that so few accidents have been reported." To us it appears to be no less remarkable than it is matter for congratulation that such has been the case hitherto. But it is probable that accidents of this nature are not publicly reported, generally, and in fact would never be heard of except when they led to very serious consequences. We should not care to witness conflagrations in this country on the same scale as in other parts of the world, in Chicago for instance. Fortunately, however, in the burning climate of India, houses in the larger towns and cities, excepting of course, native huts and *bustees*, are not generally constructed of combustible materials. But with a rapidly growing trade in this commodity, and with possibly much cheaper prices in the future, inflammable oils will be far more largely consumed and will necessarily find their way in the course of time, into every native village or hut throughout the length and breadth of this country. The necessity, then, for timely and precautionary legislation is a matter of great urgency, and on this point the committee have laid considerable stress. They say that "there cannot be the smallest doubt that oil of the kind commonly sold in Calcutta, is of a most dangerous description, and that it is essential in the interests of the public safety that such restrictions should be placed on its importation and storage as will practically debar it from finding its way into the market at all." Both in England and America very stringent restrictions are imposed on the importation and sale of low class petroleum. Why should it not be so in this country also, the need of which for protection by special legislation is far greater, considering its less favourable climatic conditions, when compared with England and America? The committee, we are glad to learn, have recommended that the Government of India should legislate, and that an Imperial act should be passed which will affect and protect, equally, every part of the Indian peninsula. Local legislation, in a matter like the present, is unsuitable, as it would be almost impossible for half-a-dozen legislative bodies, acting independently of one another, to arrive at the same results. On all the more important points there is a possible basis of common agreement, and, therefore, it is the Supreme Legislative Council which should assume the delicate duty of assimilating the law and legislating for all conflicting interests. As regards the varying circumstances of different provinces, discretionary powers may be vested in subordinate legislatures to adapt the minor requirements of the law to the actual necessities of their respective administrations. This can be readily done without disturbing the primary and essential requirements of the law. On one point, however, there should be no variation. A common standard should be adopted as the flashing point and it should be constant for all India. The committee have raised the question whether flashing point of 100° F. is not too low, and they have suggested, in the event of fresh legislation, that it should be raised; but, not to strangle the trade, they have recommended this course to be adopted, on the assumption that the comparative quality of inflammable oils will be distinguished by separate classification. And they have also recommended that some distinctive mark should be affixed to each class of oil, on the cases which contain them, so that the public may know exactly the character of the oil they may be purchasing. Various other valuable suggestions and recommendations have been made as regards the places and conditions of landing, the localities for storage, and the quantities to be stored, &c., but we cannot at present go into this part of the subject more fully. But we would impress on the Government the desirability of fostering a growing and useful trade without imposing hampering restrictions, while at the same time we feel bound to remind it that the public safety and convenience are of paramount consideration, and should not be lost sight of or ignored, when dealing with this question. Should the Government of India intend to deal with the matter in some practical way, which we trust they will, before long, we venture to hope that not only will the labours of the late petroleum committee be generally utilized, but that the gentlemen, who composed it will be unreservedly consulted before any legislative action is finally taken. And we further trust that the Chambers of Commerce of Calcutta, Bombay, and Madras, as well as the Municipal Corporation of the leading cities in India will also be invited to offer such suggestions for the satisfactory settlement of all the issues in the very important question of the petroleum trade of India.

EDITORIAL NOTES.

THE exports of wheat from Calcutta to Great Britain in May amounted to 11,989 tons, making the total exports for the first five months of this year 33,110 tons, as compared with 1,603 tons exported in the same period last year, 9,011 tons in 1878, and 88,783 tons in the first five months of 1877.

THERE was a great increase in the export trade from India to Northern Afghanistan last year, but this was due to exceptional causes; and there has been a great falling off not only in the import trade from Cabul, but in the total trade in the normal articles of commerce. The famine in Cashmere accounts for the smallness of the normal traffic to and from that principality; though, curiously enough, the returns of imports to India from Cashmere are flourishing. The statements regarding the exports of Indian and other teas across the frontier would possess more interest if their trustworthiness—a point on which Sir Robert Egerton confesses to some uncertainty—were beyond doubt. But unfortunately it does not seem that due pains have been taken to classify the teas. On the supposition, however, that the returns are accurate, there has been a decrease in the foreign and an increase in the Indian, tea exports to Northern Afghanistan. The Central Asiatics, including even the Afghans, are great tea-drinkers, and the prices they pay for the luxury are extravagant. Under more peaceful relations between India and the trans-frontier countries, the cheaper and better Indian article might supersede, or at least rival, the dearer and worse, from China.

THE Deputy Commissioner of Nowgong, in his immigration report for last year, notes that there has been a remarkable diminution in the coolies imported from the North-Western Provinces and Behar. The fact is in one way satisfactory, as these coolies have lately suffered more than any others on first arrival. It would be interesting to know whether the diminution is owing to improved circumstances in the recruiting districts (which seems probable, as the distress of 1877-78 led to an unusually large number of importations), or whether employers have shown an unwillingness to take a class of coolies so difficult to maintain at a fair standard of health. The matter is of real importance, for the tea-gardens cannot long go on drawing on the thinly-peopled regions of Sonthalia and Chota Nagpore; and, if the tea interest continues to develope at its present rate, a time will come when the vastly over-populated tract of the Behar and Benares divisions will surely form the main recruiting-grounds for Assam. Sir Stewart Bayley thinks, and with reason, that by careful attention to diet in the first year or two of their contract, this class of coolies, who are certainly not less intelligent than the "junglies" of Sonthalia and Chota Nagpore, might equally retain their health; and if a sound system of recruiting could be established in those districts, the results would be beneficial to both parties.

FROM various hints thrown out in administration reports we are glad to note that the subject of improving our crops by means of better seed has lately engrossed a good deal of attention. Doubtless the notice of Government was more immediately drawn to this by the exhaustive report on wheat cultivation in India, compiled by Dr. Forbes Watson, in which he shows that while some of the finest wheat in the world is

produced here, we also grow a large quantity of inferior sorts. He points out that the value of the various samples forwarded to him varied from 48 to 26 shillings per quarter; some were even lower than this latter, but the reduction was caused more by the admixture of other grains than by any inherent inferiority of the original sample. Now 48 is about 85 per cent. above 26 shillings, and while we cannot hope to improve all our grain to this extent, we think we are justified in expressing a hope that a general advance in value to the extent of 20 per cent. is not beyond our reach. Dr. Watson found the average value of all the samples to be 39*s*. 8*d*. per quarter, an increase of 20 per cent. on which would amount to close on Rs. 8. If the farmer only got two-thirds of this increase, which he ought to get for his improved article, it would mean an increase of over Rs. 8 per acre to his earnings, the calculation being based on an outturn of 13 bushels per acre. This, then, shows the importance of the movement. When the officials who are agitating the subject propose to utilize the bunnia as the medium of improving the seed, we join issue at once. The bunnia is the worst possible instrument that could be employed in the work, and hence we trust some other agency will be used. The bunnia cannot be depended on to sacrifice the chance of cheating the ryot *now* to the prospect of ultimate gains, and besides he has no interest in helping the ryot to become rich; his interest all lies the other way, and he fattens on the cultivator's poverty. No: let us have nothing to do with the bunnia in this connection. He is a necessary evil, only to be countenanced as a last resource, and surely the Government will be able to find suitable instruments for this work in the members of the subordinate revenue staff.

THE steamer *Pemba* arrived in Calcutta the other day with six saloon passengers, and 760 on deck. She came from the Straits and Burmah, and it is most probable that the bulk of these deck passengers were from Burmah, most likely from Rangoon. It seems to us that 760 is a very large number to carry in such a steamer, where all must pass their time for, say four days on the deck of the vessel. This, however, is a matter for the port authorities, and in all probability the *Pemba* is licensed to carry even a larger number than this. Our object in noticing the fact is not to find fault with the arrangements of the B.I.S.N. Co., whose agents are a guarantee that everything will be done according to regulation; we wish rather to point out the difference that exists in the regulations regarding the carriage of native passengers generally. Had the *Pemba* been bound for Assam with coolies, under Act VII of 1873 (B.C.), we venture to think that she would not have been allowed to carry such a number on her deck alone. The tea cooly is a pet of the Bengal Government, and as such he is particularly well taken care of, while the emigrant who does not travel under the protecting ægis of that enactment, is naturally supposed to be perfectly able to take care of himself, and rightly so. If, however, the paying emigrant can protect himself, why cannot the labour transport cooly do the same? We quite admit he is a shade lower in the scale, but any one who has had dealings with him directly, from the time the recruiter takes charge of him till he gets his contract cancelled at the end of his three years' engagement, will have no difficulty in certifying that he is able to take care of himself. Why, then, will the Bengal Government continue to coddle him to the point of strangling the great tea industry of India, which certainly has enough to contend against without having to pay over 50 per cent. more for labour than there is any necessity for?

WHILE deprecating the length of *nukshas* generally, we are tempted to make an exception in favor of those from Madras. They are usually compiled with the greatest care, and contain much that is interesting, the contents not being made up of dry statistical tables which frequently go to prove nothing, and can usually be made to prove anything. In the Madras reports no small amount of skill. is frequently spent in drawing inferences from certain occurrences, and in endeavouring to reconcile apparently incompatible conditions, and this is not done by amateurs, the work having the impress of an expert's hand on it. The area under cultivation in that province last year fell off fully two million acres, owing partly to the unfavorable character of the north-east monsoon, but more particularly to the poverty of the people who naturally have not quite recovered from the two years of famine. The outturn is estimated at a 10-anna average, which is rather low as compared with a full crop, but not so bad relatively to an *average* crop, as it is five-sixths of this latter. While the mass of the people must have benefited by the cheaper prices which prevailed generally, it must have pressed hard upon the cultivators, who had to sell their crop at these low rates, coupled with the fact that the crop was itself deficient. The price of ragi was 11·2 seers per rupee, against 11·1 during the preceding year, and rice 9·1 against 8·1. The Presidency of Madras seems to have been the sport of fortune lately in agricultural affairs, and it is to be hoped that it will, under the new *régime*, have a large increase in irrigation both by canals and wells, and a brighter day dawn on the cultivator.

THE Agricultural Department has recently issued a "memorandum on materials in India suitable for the manufacture of paper," from the pen of Mr. L. Liotard, which consists of an exhaustive summary of articles for paper-making obtainable here. Great care has been taken to give botanical names, and, where obtainable, local native names as well. One is astonished at the variety of suitable materials for this purpose obtainable in India; trees, plants, straw, and even the most common and noxious weeds are shown to possess a value in this way. It is perhaps not necessary, or with the state of mechanical knowledge presently possessed by the natives of this country, advisable, that we should recommend them to try paper-making with new products. Such attempts being more or less of the nature of experiments, might perhaps best be left to such experts as are only to be found in Europe. At the same time there does not seem to exist any reason why the natives should not import the necessary machinery to separate the fibre from the woody particles of plants, so that it might be conveniently screwed into bales, and shipped home for paper-making purposes. Among the more common plants which can thus be utilized, we find the *bhindi*—the lady's finger of our dinner-table—the stalk of which plant is peculiarly tenacious; the sunn grass, the yercum, and among nettles, the rhea grass and the common *bhang* plant. Nor is the stem of the plantain without its value in this way. The most promising article, however, seems to be the bamboo, which has already passed the experimental stage, and only waits capital and enterprise to enable it to take a prominent place among the many industries of India. Mr. Thos. Routledge, of Sunderland, England, has experimented on this fibre for some years, and we have now lying before us a sheet of paper (a sample of what can be done) made entirely of bamboo fibre, which will bear comparison with any other of a similar class in the market. From the many experiments made by Mr. Routledge he was enabled to draw the following conclusions, which are not guesses but calculations from what he has actually succeeded in doing. One acre of closely growing bamboo land will yield 40 tons of young shoots—such only being suitable; these will, when crushed, yield ten tons of dried produce, three-fourths being removed in the form of moisture. This dried produce yields 60 per cent. of fibrous paper stock; consequently one acre will produce six tons of paper-stock, and as this acre may be cropped every second year—in favorable circumstances every year—we have no difficulty in seeing that this ought to be a profitable industry. Of course a large quantity of expensive machinery is necessary to produce the finished fibre, which Mr. Routledge estimates as worth about £24 per ton. This is of course an estimate, none being in the market. He also estimates the entire cost of preparing this stock at Rs. 150 per ton. We shall be glad to show anyone this fibre in its principal stages, as well as the finished paper, both plain and printed.

MR. WEDDERBURN has proposed a scheme of agricultural reform for the Deccan, which the *Bombay Review* thus summarizes:—

There are three problems, in the opinion of the author, connected with agriculture in this presidency, awaiting solution. These are:—1st, how to reduce the present responsibility of the rayat—which he has shown himself quite unable to meet—by "adapting the assessment of the land revenue to the variations of the

seasons." 2ndly, how to keep the money-lender in his proper relation to the rayat; and 3rdly, how to secure for the state, a safe and increasing revenue. All these questions are sought to be answered in the scheme which Mr. Wedderburn purposes. In the place of the present fixed assessment, in coin, Mr. Wedderburn thinks their ought to be one in kind, a fixed proportion, say one sixteenth of the gross produce. Moreover, as a premium on improvements there should be an alternative quit-rent in kind, say three-sixteenths of an average dry crop which an enterprising cultivator who may like to irrigate and well manure his land in order to raise a garden crop may find it to his advantage to substitute in place of fixed proportion of his gross produce. The collection of this assessment should be entrusted to "zemindars," a class whom Mr. Wedderburn would create out of capitalists of intelligence and position, who might engage to pay a lump sum into the Government Treasury and realise their dues from the rayat. To increase the usefulness of this class there ought to be "kauls" (grants or concessions) executed in favour of them for fixed periods, so conditioned as to interest them in the development of the land and the happiness of its cultivator. Capital, partnership, joint-stock or otherwise will then easily flow in the direction of agriculture. But if there should be a difficulty in finding good, permanent middlemen, the Government share of the produce might be annually put up to auction as soon as the outturn for the year could be fairly gauged. But the improvement of land and the raising of garden crops requires an amount of capital, and who would advance it to the rayat hopelessly sunk in debt and utterly without credit? To meet this difficulty, there ought to be produced a mutual good understanding between the zemindar and the rayat. One of the ways of doing this would be to give a lien to the zemindar on the years' crop for the advances which he makes; this lien to be enforced by summary process before the mamlatdar. Still Mr. Wedderburn admits the rayat's way is not all clear before him. There would still be a hitch. That is the existing claims of the sowkar against the rayat, the exact extent of which, no man can tell. To move this difficulty out of the way, Mr. Wedderburn proposes that the zemindars should be allowed to buy up these debts for half their value, with money advanced by Government for the purpose. This sum could be recovered gradually from the peasant in times of good harvests and repaid to Government in small instalments, and without interest.

There is much in the above scheme which commands approval.

A CHICAGO agricultural journal gives an account of the largest plough ever known to be made, which has been recently turned out by an Illinois firm of agricultural machinery makers for use on the St. Louis Iron Mountain, and Southern Railway. It is attached to a platform car of a construction train in such a way as to cut its ditch a sufficient distance from the railway line. It will make one mile of ditch, 2 feet deep and 3 feet wide every four hours, thus doing the work of about 1,000 men. The beam is made of swamp oak, and is 8 inches by 14 inches, the land side being made of bar iron 8 inches wide and 1½ inch thick, which had to be forged expressly for the purpose. Its total weight is 1,700 lb.

OFFICIAL PAPERS.

RUBBER MANUFACTURE.

Dated London, February 1880.

From MATTHEW GRAY, Esq., General Manufacturer, India-rubber, Gutta-percha, and Telegraph Works Company, to J. R. Royle, Esq., Statistics and Commerce Department, India Office.

WE have received your letter of the 31st ultimo, and have examined the three samples of dried *Ficu* milk which you sent to us. We have no doubt they are all of some commercial value, if properly collected and carefully dried. The samples were too small for us to form any correct opinion of their value, and, we would feel much obliged to you if you could get sent to us about 100lb. of each of the three sorts, that will enable us to test in some practical manner their value.

It is of the greatest importance in collecting the milk and drying it that it be done with care and in a proper manner, so that it be kept clean, and no decomposition takes place in the drying. To do this, it is necessary that the drying be done under a roof supported by poles, to screen the milk from the direct rays of the sun. Trays for drying the milk should be made of common deal timber, say three feet long and eighteen inches wide, with side and ends about three inches high; these trays are put upon supports below the roof, and into them is poured the milk about one-eighth of an inch deep; this is allowed to remain until it is dry, or nearly dry when another layer of milk is put on top about one eighth of an inch in depth, which is allowed to dry. The process is repeated until a cake of two or three inches in thickness is made up, when it can be turned out of the tray in a dry cake of firm dry gum three feet long eighteen inches broad and two or three thick. This care in the drying of the gum may appear unnecessary to those who collect it, but years of experience has proved to us the necessity of doing it as we describe; we have found that if it is dried with the direct rays of the sun bearing upon it, decomposition takes place, or if dried in too thick a mass the outside of the mass gets dry and firm, while the centre contains moisture and induces decomposition, thereby injuring the quality of the gum very much.

PROPOSALS FOR DESTRUCTION OF THE TEA BUG IN ASSAM.

Dated Calcutta, the 9th April 1880.

From J. WOOD-MASON Esq., Officiating Superintendent, Indian Museum, to the Honorary Secretary to the Trustees, Indian Museum.

I HAVE the honour to submit a copy of an article by Professor Ray Lankester, F.R.S., which has recently appeared in the columns of *Nature*. From this article, entitled "The Destruction of Insect Pests, an unforeseen application of the Results of Biological Investigation," it will be seen that a definite line of inquiry, having for its object the destruction of insect pests, has at last been pointed out, and in the hands of Professor Elias Metschnikoff, the celebrated morphologist of the arthropora (including insects), has already yielded results exceedingly promising of ultimate success. At the meeting of the French Academy of Science, held on the 8th of the current month, M. Pasteur spoke in favour of seeking a parasite wherewith to destroy the phylloxera, as it would be easy to destroy the silkworm race by means of the corpuscular parasite of pebrine; and, in answer to an objector, showed "the possibilities of experimental multiplication of parasites," already accomplished by Metschnikoff (see Lankesters' article).

The qualifications which the man should possess who undertakes this inquiry are an extensive acquaintance with the structure, development, and physiology of arthropods, and at least an elementary, but sound knowledge, acquired by a course of practical work in the laboratory, of the structure and development of the lower fungi. In fact, he should have had a practical training in biology, and have afterwards acquired a special knowledge of insect morphology and physiology. I possess these qualifications; and I shall be willing to undertake the required investigations if the Trustees will spare me, and the Government will send me to Europe, in order that I may make myself acquainted with this remarkable application of the results of biological inquiry,—its facts but more especially its methods; and if the latter will make permanent the temporary assistance they have recently given me in the Entomological Department, shortly after my return I should be ready to go in to the field to operate against these pests. I should not be able to leave India until Dr. Anderson's return, or at any rate till about a month before that date: but in the meantime I could push on the arrangement of the entomological collections, get up the literature of the subject, and commence my microscopic work (in the course of which it is possible, though improbable, that I might discover something that would render the proposed visit to Europe unnecessary), and thus prepare myself for taking the fullest advantage of all I might learn in Europe. I am of opinion that a clear period of at least six months would be required for experimental investigation in Europe, a year at the very most.

The Destruction of Insect Pests; an unforeseen application of the Results of Biological Investigation:

"What is the good of a knowledge of microscopic creatures? What is the good of prying into the anatomy of insects? It is all very well as an amusement, but serious persons cannot be expected to assent to the devotion of endowments or State funds to such trivial purposes. Chemistry geology, electricity, if you please, have their solid commercial value; but biology is an amusement for children and old gentlemen." Such is the opinion of many a "practical man," ignorant and short-sighted as the genus invariably proves itself.

Already the practical man may be told in reply that surgery is entirely reformed by our knowledge of the minuter fungi; that by avoiding the access of bacteria to wounds, we avoid a large destruction of human life; already we see our way to avoiding some deadly diseases caused by these same bacteria, now that we know them to be the active cause of such disease. Already, silk is cheaper in consequence of our knowledge of the bacteria of the silkworm disease; already better beer is brewed, and better

yeast supplied to the baker, in consequence of Pasteur's discovery of the bacterian diseases of the yeast-plant; already vine gar-making, cheese-making, butter-making, wine-making, and other such manufacturing trades are on the way to benefit by like knowledge. Potato-disease and coffee-disease have been traced to their causes, and means suggested by biologists for dealing with the parasitic plants causing those diseases, whereby not thousands but millions of pounds sterling a year may be saved to the community.

Insect pests which have depopulated whole provinces,—such pests as the phylloxera and the Colorado beetle,—are about to receive a check at the hands of the same class of scientific students. The application of knowledge of natural facts is in this case a very remarkable one; for it is actually proposed to make use of our recently-acquired knowledge of diseases due to bacteria—not that we may arrest such diseases, but that we may promote them. Insect pests are to be destroyed by poisoning them, not with acrid mineral poisons, which damage plants as well as the insects, but by encouraging the spread of the disease-producing bacteria, which are known to be fatal to such insects. Professor Hagen, of Cambridge, Mass., has called attention to the old practice of destroying greenhouse pests by the application of yeast. He conceives that this method may be applied to other insect pests, such as phylloxera, Colorado beetle, cotton worm, &c. He imagines that the yeast fungus enters the body of the insect on which it is sprinkled, and there produces a growth which is fatal to the insect's life. It is a well-known fact that insects are very subject to fungoid diseases; and it is also ascertained that the application of yeast to the plants frequented by such insects favours their acquisition of such disease. Professor Elias Metschnikoff, the celebrated embryologist, has, however, made some investigations on this subject, and given an explanation of the possible value of yeast application (*Zool Anzeiger*, No. 47), different and more satisfactory than that which Professor Hagen appears to adopt.

The general result of the most accurate investigations of the beer-yeast fungus (*Saccharomyces cerevisiæ*) is entirely opposed to the notion that it can enter an insect's body and produce a disease. Beer-yeast is beer-yeast, and appears always (or within experimental limits) to remain so. On the other hand, De Bary has made known the life history of some simple fungi which destroy insects; and from Pasteur, Cohn, and others, we know of diseases due to those simplest of fungi, the bacteria, which produce the most deadly ravages amongst insects. Professor Metschnikoff has examined some of these minute parasitic fungi and cultivated them by passing them from one insect to another and has experimentally proved their very deadly character to the insects exposed to infection. The "green Muscardine" (*Isaria destructor*) is the name given by Metschnikoff to one of the minute fungi, the effects of which he most successfully traced. Now it is perfectly evident that if green Muscardine spores could be produced in large quantity, or spores of similar disease-producing fungi, and applied to the ground and shrubs infested by insect pests liable to harbour those fungi, we should have the best of all means for effecting the destruction of the insects, *viz.*, a poison which, once set at work, would spontaneously multiply and spread its destroying agents around.

Accordingly, Professor Metschnikoff endeavoured to cultivate the "green Muscardine" apart from insects, so as to obtain its spores, if possible, in great quantity, in a liquid which might be applied to places attacked by injurious insects. He at last succeeded in effecting this cultivation by the use of beer mash: in this decoction the green Muscardine produced a rich mycelium, and finally spores.

It is exceedingly probable that we have here the true explanation of the value of the application of yeast to plants, &c., affected by insect pests. If there are a few spores only of such parasites as the "green Muscardine" about, the fluid of the yeast will serve them for nourishment, and so cause the Muscardine to spread until it comes into contact with the insects. There is no reason to suppose that the beer-yeast plant itself is capable of generating a disease in any insects; at the same time we must remember that yeast, as ordinarily used by the brewer, is by no means pure. It contains in small quantities other minute fungi, besides the Saccharomyces cerevisiæ; and it is quite possible that a given quantity of it, say a pint, may, if the brewery from which it came were not conducted on the most perfect system such as that lately introduced by Pasteur, contain a few spores of such a disease-producing parasite as Muscardine. A diseased insect once in a way falling into the mash-tub would sufficiently keep up the supply, and thus it is possible that yeast may carry infection to insect pests and destroy them.

At the same time, Professor Metschnikoff's suggestion of a deliberate cultivation of an insect's disease-producing fungus, and the application of the cultivated fungus in quantity to places infested by these insects, is in the highest degree ingenious, and likely to give results the value of which will be estimated in thousands of pounds, and so do something to persuade "practical" men that all science is deserving of their respect and encouragement.

E. RAY LANKESTER.

ARTESIAN WELLS.

FROM W. KING, Esq, Deputy Superintendent (Madras), Geological Survey of India, to C. G. MASTER, Esq, Secretary to Government, Revenue Department, Madras, dated Bastar Territory, 31st March 1880.

SIR,—I have the honor to send you, for the information of the Government, the following notes on the Artesian Wells of Pondicherry, with considerations as to their bearing on the development of such sources of water-supply in Madras.

2. I have thought it better to burden this letter with as few as possible of the details I have collected on these wells, such being given in the technical paper which will be published in the records of the Geological Survey of India and which will be available, I trust, for reference, in May next.

3. There are three wells at Pondicherry now in thorough working order, *viz.*, and in the order of their completion:—two at the Savana and Oopallem Filatures (the work of private individuals), and the third in the Jardin d' Acclimatation, which was carried out by the French Government, under the administration of Mr. Carriol, the Chief Engineer. Besides these there is a further Government boring in operation in the Ville Noire, and I hear that another well has been opened up in the compound of Mr. Cornet, one of the proprietors of the cotton mills above mentioned.

4. The Savana well is almost 173 feet deep; its water rises to a level of nearly one foot above the surface of the ground, the discharge being at the rate of forty-four gallons a minute, and it has been flowing, with the exception of a gradual increase in the discharge for a few days, for more than two years and-a-half.

5. The Oopallem well is about 118 feet deep, with a hydrostatic level of 3·28 feet, and a discharge of 99½ gallons a minute. It has been in constant flow since the 10th of October 1878.

6. The Garden well is about 261 feet deep; it has a hydrostatic level of 4·95 feet with a discharge of 146·6 gallons a minute, and it has been flowing at a constant rate for more than a year.

7. The Ville Noire boring has been run down about 550 feet from which depth I understand that there is now a rise of water to within 2·95 feet of the surface, and a discharge of 13½ gallons a minute.

8. The well in Mr. Cornet's compound gives a gushing sheet of water at 200 feet. The water is not yet very abundant and it is only of middling quality. There is a suspicion that the oscillations of this column of water are in accord with the tidal motion of the sea. It is proposed to carry this boring deeper.

9. The three first wells discharge altogether in the year about 740,000 cubic yards of water. The water of all is fairly good, has rather a sulphurous odour and a slightly metallic tart. It is good for washing, boiling vegetables, is drunk freely by the natives, and has an average temperature of 93° Fahr.

10. On the evidence of continuous discharge and constant hydrostatic level, I am obliged to discard my speculations that the rise of the water might be due to pressure of the superincumbent strata. The wells must be as was all along contended for by Mr. Poulain, the original projector for Pondicherry, properly artesian in their action.

11. From the sections displayed by the borings, there seems no doubt but that they are entirely in the alluvial deposits, though it would appear that the deeper one, in the Ville Noire, is very nearly the next oldest rocks (for Pondicherry), *viz.*, the "Cuddalore sandstones" of tertiary age.

12. Each boring has passed through, first, a good thickness or series of permeable beds (sands, &c); next through an impermeable band of clayey beds below which comes a second thick band of sands. Beneath this again is a second band of clayey beds, below which is a third very thick and irregularly-constituted series of sands, gravels, &c., which, except in the Ville Noire, has not been pierced through by the borer.

13. The Savana Garden and Oopallem wells are in an angular line nearly at right angles to the coast, or in what may be considered as the line of dip of such alluvial strata, and though the distance between the wells are large as compared with their depth, I really think that the borings have all gone through the same zones or bands of permeable and impermeable beds. I also think that the same beds have been pierced in the Ville Noire boring.

14. Of the two bands of clayey or impermeable strata, the upper one has a dip of 1° 3° to the eastward, but the lower band is rather flatter.

15. If the upper clay seam preserves its dip or lie and is of any good lateral extent, it ought to hade up or come to the surface about two miles west of Pondicherry; and again the lower seam would, under similar conditions, crop up at about four miles further west. This is merely conjectural; there is just the possibility that these seams might behave in this way. It is not likely, however, that they would appear at the surface of the ground, there being nearly always a covering of surface soil; but they might crop up in the Ariancup river not far west of Pondicherry.

16. The water of the Oopallem well appears to rise from the permeable beds between the two thick series of clays. That of the Savana and Garden wells comes from the thick sandy and gravelly series below the second band of clays.

17. In the boring operations there were several rises, falls, and gushes of water, especially below the second seam of clays, which looks as though there were a corresponding number of water. I am doubtful as to there being so many separate sheets; and I rather take to the view that the sheets below the second band are connected with each other, the rising and falling of the water being possibly in great part due to temporary clogging of the lower extremity of the bore tube, or to the sudden opening up of new channels of communications in the permeable system.

18. The Savana waters, at the western extremity of the angular line above mentioned, have only a hydrostatic level of nearly a foot over the surface; this surface being here at 9 feet above mean sea level. At 470 yards (or thereabouts) east of this, the Garden well which draws its water from the same permeable band has a hydrostatic level of 4·95 feet, the

surface level being here 11·80 feet over mean sea level. Again, at 770 yards (or thereabouts) further east the Oopallem well has a hydrostatic level of 8·28 feet, surface being 6 feet over mean sea level.

19. All the wells, except that of the Ville Noire, are at comparatively insignificant depths as compared with the lateral extent of the alluvial beds and their supposable thickness. The quantity of water discharged by them in the year is also insignificant when compared with that absorbed in the alluvial area.

20. The borings being entirely in alluvial deposits, there is no necessity, in the present stage of artesian well-boring, to inquire as to the relations of the Cuddalore sandstones the cretaceous rocks, or the bottom gneiss n the neighbourhood of the French settlement, however much they may be adapted by their lie for holding water with a head. Indeed the depth at which the cretaceous rocks may be supposed to lie and the difficulty of boring through the hard grits and conglomerates of the Cuddalore beds above them are such as to make boring inadvisable except under very special demand for a water-supply of this kind.

21. Pondicherry is situated right up in the northern seaward corner or horn of what may be called the Cuddalore-Pondicherry alluvial plain or bay or basin. The head of the basin may be taken near the village of Allabadi, some 27 miles due west of the coast, at the point where the Pennar river enters on its proper alluvial course, though besides this water-supply there is also the Gingee river which flows across the northern part of the plain and falls into the sea as the Ariancup, close to Pondicherry.

22. The greatest breadth of the plain is about 21 miles, and then it closes in, towards the sea-coast, to a breadth of some 12 miles, between the low plateau headlands of the Red Hills of Pondicherry on the north and Capper Hill near Cuddalore to the south, after which it again widens out to the sea-beach in the horns on which the two towns stand.

23. The area may be roughly reckoned at 500 square miles, and the boundary or edge receptive of water from the adjacent rising grounds may be taken as 160 miles long. The drainage so obtained would, however, be small as compared with the amount of water brought in by the two rivers.

24. The fall or inclination of the surface from Allabadi may be $6\frac{1}{2}$ feet in the mile, though a safer rate is at $4\frac{1}{2}$ feet.

25. It has been generally assumed by Mr. Poulain and others, that the head required for the hydrostatic level must be at a good distance westward of Pondicherry, even as far back as the debouchements of the Pennar and Gingee rivers on the plain, the low rise obtained being attributed to the frictions in the passages.

26. Such are the physical conditions of the Cuddalore-Pondicherry alluvial basin, and if we are to take all these as necessary in the search for other sites for artesian wells, then the inquiry becomes limited to a great extent. Cuddalore is manifestly, on these broad and general features, the best place for a trial. There are better sites, I should think, even than this one at many spots on the seaward edges of the deltas of the Cauvery, Pennar, Kistna, and Godavari rivers; and it is not improbable that Madras may, in one view of its situation, be a favourable locality.

27. Madras is only comparable with Pondicherry, in this connection, in very few points; and, if we are to be guided entirely by the conditions of the latter place, it may be said at once that it is after all not so favourably situated for large artesian wells because, though on the seaward edge of a remarkably long belt of coastal alluvium, it is in front of only a much smaller and poorly-fed basin. The alluvial deposits are, however, not confined to this bay, but are connected to the northwest with the great plain of the Kortalayar and Narayanavaram rivers, the permeable beds of which may trend down towards and under the city. Madras is also so situated that part of the town may lie over water-bearing deposits of the Poonamallee plain, while its northern end may be over the tailing-out of the Kortalayar beds, and as proposals have already been made for sinking wells in particular parts of the suburbs, it will be as well to examine the conditions of the smaller alluvial flat.

28. The Poonamallee plain extends to the westward by a long arm, at the end of which it is again connected with the Kortalayar alluviums by a narrow neck across the Red Hills plateau towards Tiruvallur; and it sends another long arm to the south-west part, the Pallavaram Hills. Its extreme length, to the western neck, is about twenty miles, the breadth at the mouth (between the Red Hills and the Mount) being about $7\frac{1}{2}$ miles. The area including the seaward extension is about 175 square miles, and the receptive edge is not more than eighty miles in length.

29. Only two small rivers flow through it, *viz.*, those which enter the sea as the Cooum and Adyar; but it is possible that they may gather sufficient water at any rate for a small number of wells like that of Pondicherry. It is besides just possible that a fair supply of water may be taken in by the beds at the western neck from the Kortalayar water-bearing strata.

30. Indeed, unless there be an in-flow of water at this neck, I do not see how a head and service, according to the Pondicherry type, can be gained in this basin. Without it, the absolute drainage can only be relied on, and the form of the bay is such that no good length of receptive edge can be looked for much after a distance of eight miles from Madras; the further westward we look for a head beyond that distance, the smaller becomes the drainage area, in such a narrow armed bay, and the prospect of a sufficiently constant supply of water.

31. I do not, however, think that it is quite clear that such a great distance is required for the head of water at Pondicherry. It is a question with me, for instance, whether the same hydrostatic level could not be attained with a lower head at a shorter distance; there being no doubt that far more than the quantity of water discharged is obtainable in the bed of Ariancup if there be only an absorbent outcrop. The irregular oscillation of the water in the boring of the first three wells and the non-rise above ordinary well level, down to 500 feet, in the Ville Noire seem to point to a head not far distant. I find it hard, too, to believe in the impervious strata extending for any great distance westward, the few outcrops of alluvial deposits which I have noticed in the banks of some rivers having generally given indications of ultimate thinning out, in moderate distances, up, and indeed very often down, the rivers. It is again difficult for me to conceive that the borings have run down, anywhere near strata holding water absorbed in the higher reaches of the rivers within the edge of the basin.

32. I have already drawn attention to the bare possibility there is that the two zones of clayey strata disclosed by the borings at Pondicherry may bade up to the surface at beyond two and six miles from the town. The difference between the heights of the jets of the three wells is also noteworthy, as this may, to a certain extent, be due to a near head; the rises in 1,246 yards between Savana and Oopallem being, it seems to me, hardly in such proportion as might be expected with a head fifteen or twenty miles away, working in such flat deposits as these are.

33. With these doubts in my mind, I am then rather inclined to favor the view that a sufficient head and service may even exist at eight miles from Madras in the Poonamallee basin.

34. For the inclination of the surface of this plain I have only one approximate level at hand, which is nevertheless sufficient to give an idea of the height of head to be expected. The basin runs out by the narrow western neck to the Tiruvallur railway station, which is 156 feet over mean sea level; and, taking Madras at 13 feet, there must then be a fall of about 5 feet in the mile. This would give a head of about 40 feet, at the distance I suppose a sufficiently long receptive edge might be reckoned on.

35. A very serious question, however, is, as to the thickness of the alluvial deposits at Madras, and the form of the plan on which they are laid down; for the rising grounds and the rocks along its edge seem to indicate in part, a shallow and irregular bottom. There is also a record extant in the writings of the late Captain Newbold, see Journal, Royal Asiatic Society, Vol. VIII., page 2,480 of a boring or well which was made many years ago at the inland custom house, some three-quarters of a mile from the seashore, which is reputed to have struck the crystalline rocks or gneiss at only fifty-five feet below the surface.

36. The northern and western edges of the Poonamalle plain are of the "Cuddalore sandstones" of the Red Hills, which are lying at a very low angle eastwards or nearly flat, though it is probable these are denuded very evenly, and that they shelve rapidly under the plain. On the other hand, the greater part of the south side of the plain and its south-west arm are all of gneiss which goes to form the Pallavaram and Mount ridges which are in fact only part of a long promontory running north-eastward under the alluvium, perhaps still with rather a ridgy and rugged contour. It was possibly a summit of this sub-alluvial promontory, rather than a boulder of gneiss which was struck in the well noted above.

37. In any case the gneiss shelves slowly under the Adyar alluvium cropping up in the Adyar itself; hence it would hardly be advisable to run down borings along a north-east line from the Mount ridges. It is possible, of course that borings might here be run down in places to a sufficient depth, for there is no certainty about the contour of the sub-alluvial ridge, but the chances are against this. The Madras Government Farm and the Horticultural Society's Gardens are unfortunately on this line.

38. For this basin the most likely sites for wells would be in the area ranging northwest from the left bank of the Cooum between Government House and the Commander-in-Chief's Bridge towards Perambur. The alluvial deposits ought to be deep here, and the axis of any basonal lie they may have would trend in this direction. I can hardly take it on me to be more definite than this in pointing out the ground, but if I might suggest a locality for Government work, a boring in the neighbourhood of the General Hospital, the People's Park, and the Penitentiary, might strike fairly good and abundant water. For such an experiment the labor available in the Penitentiary might, perhaps, be very advantageously and economically utilized.

39. The northern part of the town is again situated on the southern seaward horn of the Kortalayar-Narayanavaram alluvial plain; and if its water-bearing strata only trend down here, then there seems every prospect of an inexhaustible supply of water which under the Pondicherry type conditions, should have a high hydrostatic level. The plain is of very great extent with wide arms up its main river and the affluents. The Nagari river has a level of about 300 feet at its entrance on the plain, and a good head must exist at the passage of the Narayanavaram river through the Nagalapuram hills. The Kortalayar alluvium proper is most remarkable in its extent, considering the present size of the river, while it actually extends right back to or is joined with the alluvial deposits of the Palar river at a point where the continuity of these is brokeny a rise of gneiss through which the larger river continues on its course to the sea. It seems probable, on this, that much of the waters brought down by the Palar may have a take-off into the Kortalayar beds at this point.

40. The doubt in my mind is as to where the Kortalayar beds do trend so far south; and again, if they do this, the far-reaching head which shall catch the head gainable in this area will not, I feel sure, be struck except by deep borings. Shallow borings such as those at Pondicherry will only strike the water-bearing strata of the Poonamallee bay, or such strata as

may crop up to the surface at a short distance in the Kortalayar arm. Mr. deClosets, C.E., of Madras, has, I think, stated in a letter to Government that he struck a sheet of rising water in the Napier Iron Works at 90 feet, This had not a gush over surface level, but it was a promising sign as all the Pondicherry wells have shown these preliminary rises. However, to gain a hydrostatic level of any height in Madras it would seem, in any case, that the boring must be run down for at least 300 feet, for the best height, attained at Pondicherry is only sixteen feet over mean sea level at a depth of 261 feet.

41. It would be better that any borings likely to be carried out in the northern part of Madras should be to the west of the canal and north of Rayapuram railway station, though it would be almost worth risking the chance of missing any sub-alluvial ridge of gneiss if a well were tried for in the western half of Black Town.

GOLD IN THE WYNAAD.

From R. Brough Smyth, Esq., Mining Engineer, to J. H. Garstin, Esq., C.S.I., Acting Secretary to Government, Revenue Department, dated Mangalore, 2nd March 1880.

I have the honor to submit the following report for the consideration of his Grace the Governor in Council.

2. I left Mangalore at 6 P.M. on the 8th February and arrived at Karkal on the 9th at 4° 30 A.M.

3. On the 10th, I was engaged in examining the country and in making inquiries respecting the occurrence of gold in this area; and the Sub-Magistrate, and all others who were questioned, stated that they knew of no gold workings, and that they never heard of gold having been found near Karkal. White stone (quartz) was, however, I was told, to be seen at Tallar and Miar.

4. *Tallar.*—This spot is about two miles north-eastward of the bazaar. The bed-rock is gneiss and granitoid gneiss; the foliation obscure, but where observable about N. 50° W.—S. 50° E. The soils are poor and of variable thickness, the colors being pale chocolate and light yellowish and reddish brown. Numerous fragments of country-rock, and small angular pieces of quartz are scattered on the surface, and found also rather abundantly in the soil wherever it is dug up. In the valleys the soils and the bed-rock (the latter to some depth more or less decomposed) are nearly of the same color. At one spot on a low ridge there are larger fragments of quartz, and they cover a considerable space, all derived from what may be a vein, the situation of which is indicated by outcropping blocks. It was not possible to ascertain the direction of the vein or band without making an excavation; and as no gold was found in the soil, after repeated trials, I did not think it desirable to undertake any works in this locality. Northward of this ridge, on the edge of the valley, where a deep ditch has been cut, the bed-rock is well exposed. Throughout a thickness of fifteen feet it is intersected by veins of quartz from one to twelve inches in width; and wherever a cutting is made similar veins, usually less numerous, are found. One small vein or "leader" was seen to strike N. and S. and to dip W. at a very low angle. The soils near those veins were washed and not a particle of gold was seen. All that remained after washing was a small quantity of yellow sand with minute specks of sesqui-oxyd of iron. Specimens of the quartz were collected for subsequent treatment by amalgamation. The quartz is everywhere of the same character; it is milk-white with translucent patches, and in places crystalline; it is not mineralised; no pyrites were seen in any place, and it bears no resemblance to the auriferous quartz usually found in Southern India. Some of the quartz was broken on the spot and in none was gold visible under the lens.

5. *Miar.*—About one mile eastward of Karkal there is an out crop of quartz extending for a length of one hundred and fifty yards. The direction of the vein is N. 30° W.—S. 30° E. The thickness probably does not exceed five feet in any part. Several dishes of earth were washed here and not a trace of gold was discovered, nor was any gold seen in the quartz. Pyrites and other minerals generally found with gold were absent.

6. *Mooroor.*—Near Kookund oor, about 2½ miles from Karkal, is a hill named Mooroor. The hill is a bare blackened dome-shaped mass of gneiss with a thin covering of the so-called laterite (detrital) at its base. Intersecting this rock are (rarely) thin veins of crystalline quartz and one, from half an inch to four inches in thickness, running in a straight line, has a direction N. 72° W.—S. 72° E. There are rather large crystals of felspar impacted in the rock, giving it in places a porphyritic character, but it is strictly a granitoid gneiss, many hand specimens being exactly similar to an ordinary ternary granite. And the thin veins of quartz are like those usually seen in granite. About two hundred yards south of the base of the hill is a rather large exposure of micacised crystalline quartz; its direction being, as nearly as could be ascertained N. 7° E.—S W. The thickness and dip could not be measured. It is seen only where a cutting has been made, but the low rise near it is strewn with fragments of quartz.

7. These areas have none of the characteristics of auriferous tracts, and no native workings were seen in any place.

8. On the 15th February I left Karkal on my way to Mijar, and I was compelled to remain at Mudbidiri until the 17th, as a shelter of sticks, boughs, and leaves had to be erected at the old "diggings" near Mijar for the accommodation of myself and Mr. Thomas Laing, and to afford protection also to the stores, tools, instruments, and furniture which I had to carry with me. The native officer at Mudbidiri, I am sure, did his utmost to get the place prepared as soon as possible; and from its appearance it was probably the work of a few hours. It afforded some slight protection from the sun during certain hours of the day.

9. I arrived at the diggings on the 17th at 3° 45 P.M., and at once commenced an examination of them. The hill—Munda-bettu—is distant about two miles from the village of Mijar, and its summit is only sixty feet above the valley or "flat" on its south-western side. The bed-rock, before it was disturbed, was covered with soil and gravel to a depth of a few inches on the summit, gradually thickening towards the base; at the foot of the hill in the valley the thickness of the soil, gravel, clay, &c., is twelve feet.

10. Subsequently during my stay at the old diggings the hill and the neighbouring ranges were diligently prospected.

11. The form and position of Munda-bettu will be best understood from a sketch-plan and section:—*

12. The auriferous soil and detritus on Munda-bettu are composed of loam and clay with small water-worn pieces of country-rock, fragments of laterite mostly in the form of hematite and limonite and small angular pieces of white and ferruginous quartz. Those have been derived partly from the disintegration of the bed-rock and partly from the laterite.

13. The area actually worked by the natives is not more than one acre and-a-half, and much of it seems to have been turned over several times. At one spot the bed-rock is laid bare over a space of several square yards, and it was here, it is said, that gold was got in considerable quantities. The surface of the bed-rock is irregular—grooved, so to speak, downward from the summit—and there are consequently variations in the depth of the soil. Water was conserved in shallow excavations, and used either for sluicing or for washing the earth in the wooden dish. There are heaps of "tailings" lying on the surface.

14. The natives at Mijar say that no profitable work has been done during the past two or three years; that few of them ever mind on the hill; and that nearly all the work was done by men who came down from the ghats. Near what is supposed to have been the richest "patch" some earth was taken by Mr. Thomas Laing and washed, and one rather coarse speck of gold was found together with some finer particles.

15. The hill was prospected by cutting sections across it at different levels, and by making excavations on and near its summit and by sinking pits down to the bed-rock on and near the "flat."

16. Earth was taken from all these places and washed. Nineteen dishes of soil from various parts of the hill showed a few minute particles of gold; of five dishes from the summit one only gave a speck; and one dish from a new cutting near the summit showed no gold.

17. A pit was sunk on the "flat" where I was certain I should find undisturbed ground and thus get a correct section, and it showed the following layers from the surface downwards:—

		Ft.	In.
1.	Loamy soil	0	6
2.	Sandy clay and gravel and a few small pieces of carbonised wood	7	6
3.	Harsh, dry, mealy loam fine gravel (greyish-brown) (auriferous)	1	3
4.	Clay, with pretty large water-worn pebbles of quartz, country-rock, laterite and hornblende rock	2	3
5.	Yellow and mottled clay resting on bed-rock (decomposed)	0	6
		12	0

As soon as the bed rock was reached water came in, but only in small quantity. The auriferous stratum (No. 3) was not rich. Fourteen dishes were washed and thirteen showed gold. The clay (No. 4) contained a few particles of gold; of three dishes washed two gave a few specks, and one none. The decomposed bed-rock (in the condition of wet clay) yielded no gold.

18. Earth taken from a shallow hole sunk near the head of the "flat" and "bottomed" at a depth of four feet was almost non-auriferous four non-auriferous: four dishes were washed and one only showed a speck of gold.

19. The slopes of the ranges near Munda-bettu and the edges of the paddy flats for a considerable distance on both sides were carefully prospected. Holes were sunk and excavations made at various points. Forty-one dishes of earth were washed and only twelve gave, in each case, minute specks of gold. Indeed it was barely possible, very often, to see the gold with the naked eye.

20. There is a band of talcose schist running through the hill, but near the hill the rock is the ordinary hard gneiss of the country, and though it contains quartz, it is not intersected by reefs or veins. The direction of the foliation observed was N. 75°—80° W.—S. 75°—80° E.

21. On the hill there is an irregular band of quartz of no great extent, and running out altogether not many yards from the spot where it is from eighteen inches to two feet in thickness. It is probably not a vein, but

* We are sorry, we cannot reproduce the sketch.—Ed., I. A.

merely an example on a larger scale, of the thin intercalated bands of quartz which coincide with the direction of the foliation.

22. A great deal of the quartz and ferrugino us conglomerate was broken and carefully examined for gold, but none was seen, nor was any found after it was pounded and washed.

23. A few pieces of pale rose-coloured and amethystine quartz were found probably indicating the presence of manganese, iron, and titanic acid. Black oxyd of manganese in minute quantities and small scales of chlorite, talc-chlorite and very small patches of iron pyrites are associated with the quartz, but not commonly; and grains of titanic iron and magnetic iron remained in one or two dishes after "washing off."

24. The natives appear to have entirely neglected the quartz and to have sought for gold only in the detritus lying on the slope of the hill. They say that the gold was found in the "ironstone."

25. The hills immediately above Munda-bettu are covered with a deposit of the so-called laterite. The features presented, more particularly when viewed from a distance, are exactly similar to those seen in volcanic tracts; the laterite where not affected by denudation forming high level plains, and where affected by denudation leaving in many places flat-topped hills, whose character, when the nature of the formation is known, cannot be mistaken. I carefully examined the laterite in the neighbourhood of Mijar and I found it to vary in character. In one place it is almost a conglomerate with much nodular hematite and limonite. The latter minerals are also mammillary and concretionary, showing that chemical changes have taken place since the rock was deposited. It is elsewhere quartzose, and again appears as the ordinary ferruginous clayey rock which is cut and used for building purposes. Not far distant from where the rock is conglomeratic the natives were cutting slabs.

26. The edges of these high plains present a peculiar feature. The rains have carried away the earth and partly undermined the laterite on the edges of the plains, and it has fallen away in blocks and rolled down the hills, and where but slightly moved it appears as bands eight or ten feet in width, separated from the mass forming the plains by deep narrow spaces, and not unlike what would present itself if channels had been cut by man.

27. As far as I could observe, the thickness of the deposit does not in any part exceed twenty feet, and it rests on hard dense undecomposed gneissoid rock.

28. The formation appears to have a slope towards the sea. Lithologically some hand specimens do not differ from the recent fossiliferous marine tertiaries of the southern part of Australia—thin deposits which were formed in shallow water.

29. The laterite plains were once continuous over many miles of country as evidenced now by the flat-topped hills widely separated from one another.

30. I examined this formation also at Gunnymutta, where the same features are seen. Near Gunnymutta and below the level of the laterite and separated from the adjacent hills by a narrow valley is a dome-shaped mass of granitoid gneiss; much of it not distinguishable from granite when broken in small pieces, but its true character is easily seen *in situ*. The direction of the foliation is N. 50° W. It weathers in large flakes, from two to several inches in thickness, conformable to the line of curve of the dome, and is thus easily quarried.

31. The earth lying immediately beneath the laterite and the laterite pounded (from different localities) were washed, but no gold was found in them.

32. Great difficulties presented themselves in attempting to prospect at Mijar. Water could be got only from wells, and I found it impossible to procure sufficient labor. Sometimes I had two coolies, sometimes four, and occasionally six. The men were old and feeble, and apparently unaccustomed to work with the mamoty and pick-axe.

33. On the 1st May 1868, the Acting Collector of South Canara reported that different applicants had offered as much as Rs. 200, 600, and 600 for the privilege of working the hill known as Munda-bettu, and that one native had offered to pay a higher rent than all the other applicants.

The offer of Rs. 600 was for the exclusive right to work the whole of the hill for the period of one year and-a-half. These offers were made probably either for the purpose of sub-letting or under the belief that the whole hill would prove as rich as the patch first found. The natives are superstitious, and they no doubt firmly believe in the legend* connected with the discovery of gold on the hill, and it is therefore not surprising that they made such offers as those described. Moreover there may be small patches of rich earth as yet untouched on Munda-bettu and on the neighbouring hills, but it would be only possible to discover these, if they exist, during the monsoons.

34. The result of my examination of this area of country is that it is not likely to yield gold in such quantities as to induce Europeans to undertake mining enterprises, it is not intersected anywhere by quartz reefs in the places seen by me, and I cannot learn that quartz reefs have been found by any one.

The alluviums during the monsoons will no doubt be worked by natives who are not able to obtain employment at ordinary wages; and they may, perhaps, occasionally find more than sufficient gold for their support, but few will abandon their ordinary occupations to follow gold-mining at Mijar.

35. I have received every possible assistance from the officers of the Government in this district. Mr. W. H. Comyn, the Collector, instructed his subordinates at Karkal and Mudbidiri to give me such aid as I required, and I am greatly indebted also for the prompt and friendly help rendered by Mr. B. C. Leggatt, the Treasurer, and Mr. Herbert Bradley, the Assitant Collector.

36. During the period of my stay at Karkal and Mijar, Mr. Thomas Laing washed altogether one hundred and seven dishes of earth and pounded rock.

37. I left Mijar on the 29th February, and arrived at Mangalore on the same day at 4 P.M.

* The following account of the cause of the occurrence of gold on Munda-bettu is given by the Jains:—"Many years ago treasure was hidden by the Jains on the Western slope of Munda-bettu. It lay there a long time. About twenty-two years ago a dreadful thunderstorm occurred and the hill was 'struck by the thunder;' the treasure was melted and spread over all the hill. Then men came and saw it in the morning, and one found a piece of melted gold. After that men dug for gold.

SELECTIONS.

DEATH OF ROBERT FORTUNE.

We have to announce, with deep regret, the death on the 13th April of the distinguished Eastern traveller and plant collector, Robert Fortune. He was born on the 16th September, 1812, in the parish of Edrom, Berwickshire. After receiving a good education at the school in his native parish, he served an apprenticeship in the gardens at Kelloe House, in the same neighbourhood. He then proceeded to Moredum, near Edinburgh, as a journeyman gardener, and from thence he entered the Botanic Gardens of Edinburgh, then under the charge of the elder McNab. From here he went to London in 1842, where he received the appointment of Superintendent of the hothouse department in the gardens of the Royal Horticultural Society at Chiswick, then in the heyday of their greatest eminence. In 1843 the Society determined to send a plant collector to China, and selected, Robert Fortune for the important post. How well he fulfilled his mission is well-known to every admirer of plants, by the great number of highly ornamental as well as useful species which he has been the means of introducing to this country during that and successive journeys to the East. In 1848 he returned to China, being commissioned by the East India Company to introduce the tea plant from China to India, which he successfully accomplished in 1851. He again visited China in 1852, and in 1858 he travelled through Northern China and Japan. In the course of these journeys, extending to from two to four years, he discovered many new plants, which he sent home generally with the greatest success, considering the long distance and the numerous accidents to which such delicate subjects are liable in the course of a long sea voyage.

Many of these introductions are now to be seen in prominent positions in every collection of plants in the country, and will long be looked on as living memorials of the steady perseverance and indefatigable energy of Robert Fortune. From stately tree to lowly herb they all attest the distinguished ability, good taste, and industry of the famous Collector.—*Journal of Forestry.*

INDIGO IN THE NORTH-WEST.

We are glad to hear that the Agra Canal has begun to tell favourably on the production of indigo in this part of the country. So readily have the villagers along its banks taken to growing the plant, that *gâd* (the dye in its uncooked state) is a regular article of commerce with the Hattras mahajun, who come down to Agra to make advances for it. One of these gentlemen gives us some interesting information of the profits to be derived from this business. A maund of *gâd* costs from Rs. 14 to Rs. 15. It takes from 8 to 9 maunds of *gâd* to make a maund of manufactured indigo, such as is sold in the Calcutta market. The cost of the latter by this process is therefore about Rs. 125 a maund. Last season our informant manufactured 72 maunds at the above rate, and sold them at Rs. 207-8 in Calcutta, netting a nice little profit of Rs. 6,000 on an outlay of Rs. 9,000 only.

The advantages of this system are that the manufacturer is free from the risk attending the growth of indigo on his own account. As long as the cultivators to whom he advances money for the production of *gâd*, are solvent, he is safe. Judgment no doubt is required in making such advances, but we believe that a class of middlemen (*arutheas*) can always be found who will guarantee the re-payment of such advances for a small commission. The only other requisite is a factory containing a boiler, presses, &c., adapted for converting *gâd* into manufactured indigo, but these can be found in any numbers in the Upper Doab districts. For instance, the once famous concern of Chotwa near Hattras is in the market and affords every facility for such work. It contains, we believe, nine factories, and is the property of the present proprietor of the *Englishman* newspaper. Near half-a-century ago, Chotwa and the Saunders were a landmark in the N.-W.P., and it seems a pity that in these days of railways and canals, the enterprise of indigo-planting should have fallen into discredit with the European community of these provinces, while it is being prosecuted vigorously by the native.—*Delhi Gazette.*

JUTE PAPER MILLS.

A PROPOSAL has been made to the Secretary of State for India, by Messrs. McCorquodale & Co., to erect a mill in India for the manufacture of paper made from jute, and to contract for the supply and printing of the same in such forms, &c., as may be required, provided a sufficient inducement be offered to them to undertake its manufacture in India. This paper Messrs. McCorquodale & Co. state to have been used for many years in connection with some of the principal railways, and it was, some three years ago, through the influence of Mr. Rowland Winn, M.P., adopted by her Majesty's Stationery Office, thus effecting a considerable annual saving by the change. They add that the mill which they would erect could also produce other descriptions of paper now purchased in England for use in India. After due inquiry of experts and officials, the Secretary of State informed Messrs. McCorquodale & Co. that the attention of the Government of India has recently been directed to the importance of obtaining, if possible, in India, paper of local manufacture for official use. In the event, therefore, of additional paper mills being established in India by competent manufacturers, he said that the Government of India would no doubt be prepared to extend their local purchases of such paper provided that, in quality and price, it did not compare unfavourably with imported supplies. The Secretary of State added that if Messrs. McCorquodale & Co. were desirous of prosecuting this matter further, it would be more convenient that they should address the Government of India direct, by whom all contracts for local supply are arranged, and it would assist in the consideration of their proposal, if they were able to state, at least approximately, the weight, quality, and probable price of the paper which they would propose to supply.

MALWA OPIUM.

THE Agent to the Governor-General, in Central India makes some remarks about the trade in Malwa opium, the revenue from which forms so important a factor in Imperial receipts:—

For the ten years ending 31st March 1869, the total number of chests passing the scales was 341,412, the duty realized being Rs. 20,11,04,500. For the ten years ending 31st March 1879, the books show a total export from Malwa of 405,091 chests, representing in duty paid to Government Rs. 24,57,82,725. The improvement, therefore, over the previous decade is 63,682 chests, and a revenue of Rs. 4,46,78,225—in other words, the increase in export is more, on an average, than 500 chests a month, and the yearly revenue to Government has improved by upwards of forty-four lakhs of rupees.

Among the causes of improvement in this important trade I would mention the security of the country and a decrease in highway robbery and violence; inducements held out by Chiefs, to whom land under opium is the chief sources of income, improvements in communication, and particularly the facilities which the railway from Indore and Ujjain, affords. The establishment of scales at Ujjain, Jaora, and Udipur has been the means of drawing the produce of each district to pay export duty to the Government of India without being harassed by the levy of dues by each State through which the opium passed, as was the case when Indore was the only place in Malwa where Government duty could be paid.

The importance of opium cultivation to the Chiefs of Malwa can hardly be over estimated—it gives a value to land which no other crop can afford. Wheat and other cereals in the best soil pay from As. 12 to Rs. 3 per beegah; opium yields Rs. 10, Rs. 20, and Rs 40 for the same measure of land, and in some districts where the advantage of soil and water are great and the opuim crop heavy, as much as Rs. 60 per beegah is paid for land under the poppy.

The principal gainers by the growth of opium are the Maharajah's Sindia and Holkar. In Indore Territory especially, advantage has been taken of the profits which the trade in opium holds out to increase the assessment on irrigated lands, and Holkar's revenue has, chiefly by this means, steadily increased. Enhanced collections may fairly be estimated at 40 per cent. over those of 1868.

A NEW CEREAL.

BRITISH farmers will receive with mingled feelings the intelligence that a new cereal has been discovered in Kansas, and that this fresh addition to the weapons with which the agriculturists on the other side of the water attack our market is a peculiarly nutritious and hardy production. In appearance it is something like a grain of wheat, each kernel being enclosed in a separate case, and as food—as a flesh-forming substance—it fully ranks with wheat. There, however, unhappily for all corn that has hitherto been recognised by the farmer, comparison ends. It is as tenacious of life as the proverbial cat, and therein lies its value. Planted in ground upon which rain had not fallen for eight months, it sprang up at once and yielded, in face of five weeks' additional drought, a crop of sixty bushels to the acre. When tested as a means of support for cattle, its stalk was found to be not only nutritious but so attractive to the animals that they seized upon it with an avidity that surprised all spectators while, when thrashed out, its yield was so great that in the opinion of the State Board of Agriculture it bids fair to supplant maize rice corn, pampas corn, and Egyptian wheat. An enthusiastic American agriculturist now contemplates its importation into England with great glee, and thinks that its appearance will give the 'death-blow to British prejudice.' If, in exchange for what this gentleman terms 'British prejudice,' we receive a grain that will grow without the adventitious aid of rain, we shall scarcely lose by the bargain.—*Daily Telegraph.*

CARDAMOMS.

AS we feel sure that Cardamoms will soon become one of our recognised staples, we will offer a few remarks on the subject. The Malabar variety of Cardamom is sometimes found in our jungles, but is not indigenous to Ceylon. The seeds have possibly been dropped by sawyers or others at work in the jungle, and the plant would naturally thrive in humid and shady hollows. It is very like the Ceylon Cardamom in leaf, though shorter and softer on the under side, and is nearly allied to the ubiquitous wild ginger. Let those who buy from the natives (they are worth about Rs. 30 per thousand,) test them by the raceme rather than the root and leaf; in case this is not to be had, we may say that the root is white, and that in all but the true variety there is a distinct red line at the springing of the leaf-stalk from the stem, which is not seen in the Malabar kind. The elevation best suited is from 3,000 to 3,500 above the sea; the rainfall should be not less than 120 inches in the year, and the soil should be light and free. Care must be taken that the stools be not separated before they are delivered, as this is an operation that requires care and supervision; the best plan to do this is to place the stool on the hand and allow it to *fall* naturally to pieces so that the roots for the *planting out* (having if possible two or more stems or at least eyes on each) can be care fully and gently separated; do not cut the stems, but rather plant them out untouched. It is not advisable to burn the undergrowth after clear ing, the best plan being to heap it. In felling, the shade to be aimed at should be chequered or acacia-like, such as that of the Ingasaman and Flamboyant. In good soils we suppose seven feet apart, to be the most suitable distance to plant: this would give, in round figures, 900 stools to the acre. It is a mistake not to hole, although deep holing may be unnecessary, great care must be used in planting, deep planting is suicidal; the day chosen should be a dull, dry one, and as little stamping-down as possible should be allowed; with all care, however, the first attempts may be disappointing; we know of a case where, even after all apparent care, seventy-five per cent. of the bulbs failed. It is most advisable to put out 'virgin' bulbs, as they save a year in bearing, and we should strongly advise bulbs in preference to seedlings, as the latter would lose two years, a very important consideration in this special product, as we shall point out. The clearing must be carefully weeded and supplied and at the end of the third year, provided the bulbs were young and vigorous, will be the first picking. The fruit grows along the ground in long racemes, each raceme having about ten branches; sometimes, but very rarely, the plant throws out fruit at the top, when this happens the rhyzone should be carefully kept and propagated; immediately surrounding the plant, and under the racemes, the ground should be swept, all stones, dead stems, and other rubbish being removed: this will, in a degree, keep the fruit from the attacks of insects, &c.—almost every creature bi-pedal or otherwise, seems to be its natural enemy,—and will enable the picker the more easily to get at the raceme. The most successful plan we believe, is to take off the fruit when not quite ripe, by cutting the stems as near the raceme as practicable, with scissors; if the fruit is picked too ripe it is an impossibility to cure without the capsule splitting: the best pickers are women and children, and each child, when the clearing is in full bearing should bring in 6 to 8 lbs. a day of green fruit. Up to this point the cultivation though harassing, has been shown to be simple and straightforward, the next process—curing—is by no means so, however. The method most successfully adopted in Ceylon is to keep the capsules till they are partially dried under light shade such as that of coir-matting and gradually removing it; they should never be exposed to very hot sun and at the same time carefully guarded against mouldiness. The colour that is most appreciated in the London market is yellow or 'golden,' and not white as some people suppose; the pods should be heavy, short, and round, all split ones being carefully picked out. After thorough drying, the "heads and tails" are cut off by children who will finish about 3lbs. each daily. There is little doubt that until the home market is supplied, and at present it certainly is not, the London prices will remain very high: well cured, heavy clipped cardamoms have fetched 8*s*. 7*d*. quite recently, it is therefore evident that these fortunate ones first in the market have much cause for self congratulation. The market of the future is India, specially in the North, where there is a large and increasing demand for the Malabar kind. Owing to this fictitious state of the market statistics are unreliable; we have known, at least one magnificent and giant rhyzome give as much as 20lbs. green fruit, and we must leave it to our readers to calculate for themselves the enormous yield and consequent profit per acre of this product, only adding that the green capsules dry down to one quarter of the original bulk, and that the present price in Colombo for well cured high grown Cardamoms is Rs. 2·50 to Rs. 3 per lb.—*Ceylon Times.*

COCKCHAFER GRUBS.

THE idea of poisoning Cockchafer grubs by preparations of arsenic is worthy of attention and practical experiment. It is quite conceivable that a quantity of mineral poison so small as to have no deleterious effect on vegetation, even the tender feeding rootlets, may yet be quite sufficient to act fatally on such insects as grubs. Any effect on the fruit of the trees, from sulphate of lime with so slight an admixture of arsenic, is, of course, out of the question. The difficulty would be to get the coolies to apply the remedy without doing themselves harm. But initiatory experiments will, of course, be carried on by superintendents, or under their immediate inspection.

In an American work, "Curious History of Insects," by Frank Conway (J. B. Lippincote & Co., Philadelphia), we find a notice of the cockchafer and its grubs, confirmatory of the opinions formed of their destructiveness in the case of perfectly healthy vegetation. The winged insects, it seems, are called not only *cockchafers* but *hedgechafers*, *May-bugs* (*bug* is, in the United States, the generic term for insects) and *dorrs*. The latter name is traced to the "Irish" *dord*, humming, or buzzing; or it may be derived from the Anglo-Saxon *dora*, a locust or drone. Fabricius included the chafers in the genus *Melolontha*, a word which retains an odd notion of the Greeks that the insects were produced from or with the flowers of apple trees. The Swedish peasants call the grub *Bemärkelse-mask*, prognostic-worm, from their belief that the varying colour of the creatures (they are bluish when well stuffed with food) indicates a mild or a severe winter. A more absurd notion is prevalent in England (of course confined to the ignorant) that these beetles are changed into briers. In 1575, the river Severn carried down enormous numbers of these creatures, the explanation given being that "the water overflowing the low ground brought the beetles for air to the surface, whence they were swept by the current." In 1688, cockchafers appeared in, such numbers in Ireland that the air was darkened by their flight, and the noise of their humming resembled the beating of drums at a distance :—

"*The grinding of leaves in the mouths of this vast multitude altogether made a sound very much resembling the sawing of timber.* In a very short time after the appearance of these beetles in such immense numbers, they had so entirely eaten up and destroyed the leaves of the trees, that the whole country, for miles around, though in the middle of summer, was left as bare as in the depth of winter. During the unfavourable seasons of the weather, which followed this plague, the swine and poultry would watch under the trees for the falling of the beetles, to feed and fatten upon them; and even the poorer sort of the country people, the country then labouring under a scarcity of provision, had a way of dressing them, and *lived upon them as food*. In Normandy, according to Mouffet, the cockchafers make their appearance every third year. In 1875, many provinces of France were so ravaged by them, that a premium was offered by the Government for the best mode of destroying them. During this year, a farmer, near Blois, employed a number of children and the poorer people to destroy the cockchafers at the rate of two liards a hundred, and in a few days they collected fourteen thousand. The County of Norfolk in England seems occasionally to have suffered much from the ravages of these insects, and Bingley tells us that about sixty years ago, a farm near Norwich was so infested with them, that the farmer and his servants affirmed they had gathered fifty bushels of them; and the grubs had done so much injury, that the court of the city, in compassion to the poor fellow's misfortune, allowed him £25."

How many times would £25 compensate the "poor fellows" of Ceylon planters for the damage done to their interests by these "blind beetles?"

THE HISTORY OF THE MEXICAN FIBRE.

THE brief notice given in your last number of the growth and production of Sisal hemp leads me to believe that some account of another Agave product of commerce may prove interesting, and, as I have had much to do with its extensive introduction and use, and a few years ago made a tour of inspection over the wild unexplored parts of Mexico where it is grown, I have much pleasure in placing before the readers of your widely circulated and useful journal the following particulars, which chiefly relate to what is generally known in commerce as Mexican fibre:—

There is still very much doubt as to which is the particular species of Agave which yields this so-called Mexican fibre, and whether it is not obtained from several varieties or species of the genus. I am not sufficient botanist to determine this question. My knowledge being chiefly restricted to the commercial quality and character of the product.

The leaves of *Agave Americana*, Lin., and some other species, such as *A. Mexicana*, furnish a strong fibre adapted for ropes, and even for beautiful textile fabrics. The pithy stalk can be utilised for some of the purposes for which cork is usually employed, for instance, to form the bottoms of insect cases, &c. Where space and circumstances admit of it, impenetrable hedges may be raised in the course of some years from Agaves.

It is under the tropics proper, throughout Mexico, Central America, the Nothern States of South America, and in the West Indies that the Agaves are most abundant, and may be multiplied to any extent necessary to meet the demand of the world for the kind of fibre which they produce.

The fibres extracted from the Agaves differ widely in fineness and consequently value, although all are available for cloth, cordage, and paper. The quality of the fibre, it is said, also varies considerably with the age of the plant, being most pliable and easily worked if taken when the plant is young. Superficial writers and travellers have caused great confusion and uncertainty in respect of the Agaves by confounding the different species, and their contradictions have much embarrassed practical men in their calculations and efforts for utilising them.

According to some writers the plant that furnishes the Sisal hemp, the Chelem, Henequen, and Sacci of the Mexicans is *Agave rigida*, Miller, *A. Ixtle*, Kauvinsky. Drs. Perrine, Scott, and Engelmann indicate several varieties of this stately plant, the fibre being therefore variable both in quantity and quality. The yield of fibre begins at four or five years, and lasts for half a century or more, the plant being prevented from flowering by cutting away its flower-stalk when very young. The leaves are from two to six feet long and two to six inches wide; the flower stems attain a height of twenty-five feet if suffered to grow, the panicles of flowers about eight feet long, bearing in abundance bulb-like buds.

Other large species of Agave, all fibre-yielding, are *A. antillarum*, Descourtel, from Hayti; *A. Parryi*, Engelmann, from New Mexico; *A Palmeri*, Engelmann, from South Arizona, up to an elevation of 6,000 feet.

About thirty years ago a small sailing vessel arrived in Liverpool from a Central American port. One of the crew had brought with him a bag which he used as a pillow, containing a small quantity of what is known as Mexican fibre. On landing he sold it for a trifle to a working brushmaker in Whitechapel, who made it up into scrubbing brushes. A few years after, small shipments of this fibre commenced to arrive at Liverpool and New York from Tampico. Attention was prominently directed to it in this country during the time of the war with Russia, when, bristles becoming scarce, the brushmakers were at their wits' end, and all strong descriptions of vegetable fibre, such as this Agave fibre, piassava or bass, kittool, cocoa-nut coir and other substances were used, and have since held an important place as brush-making fibres.

I was in Manchester at that time, and a firm on which I had called to do business in other fibres, drew my attention to a sample of this Mexican fibre, which had been sent to them as probably suited for a substitute to hemp and jute. They said, however, it was useless for their trade, the fibre being too stout and strong. I immediately went to Liverpool to consult the house I represented, and pointing out how admirably this fibre was fitted for brushmaking, we not only bought up all on hand but sent to New York to secure what was on sale there. Samples were then sent to all the brushmakers, in the kingdom for trial, and finding it was a good substitute for bristles, large orders were obtained, and the price of the fibre rose from £28-10 to £70 per ton. I took over samples to show brushmakers of Belgium, Holland, and Germany, but not one would look at the fibre, even when shown the excellent brushes made with it.

I even offered to present them with a hundredweight of the fibre that they might test it; one firm alone consented to accept it, but I had not gone far when they sent for me and refused to do even this, unless I paid the freight also. This I declined. At present this firm employs a very large number of hands in making brushes with this fibre. Hearing at Bremen that a lot of this fibre was lying unsold at Hamburg, I went there and secured it. The trade gradually began to appreciate the fibre and large quantities were used. It was also employed mixed with pig-hair for stuffing chairs, mattresses, etc. Great fluctuations have taken place in the price of the fibre, it has been sold as high as £100 the ton, and as low as £28, and it sells now at about £40 per ton.

The use of this fibre in brush-making now gives employment to thousands of people not only in the United Kingdom and on the Continent, but in Australia and America. In the form of scrubbing brushes it is to be seen in almost every grocer's, chandler's, and retail ironmonger's shop, and cheap nail brushes are also made of it and retailed at 3*d*. or 4*d*.

In 1874, in a commercial tour to the West Indies and Mexico, I made it my especial object to penetrate far into the interior of Mexico in order to ascertain for myself its mode of growth and preparation.

When I arrived in the interior over the mountains, I found large bunches of the plants growing wild from three to five feet apart. The plant is called Lechuguille by the natives here. The mode of obtaining the fibre is simple, and the rude implements required very primitive. They consist of a stick about four feet long, to the end of which a leather thong is attached, something like a huntsman's whip. This is slipped over the top of the leaf and serves to detach it. The leaves have serrated edges or spines down each side. When detached, they are passed to a man sitting on the ground with a strip of board before him about two feet long. This man scrapes the end of the leaves and removes the pulpy part, and he then begins to scrape the other part with a heavy iron knife, placing, when possible, one end of the knife under the root of a tree or shrub to get a leverage, by which means the pulpy matter is removed, and he has a small handful of beautiful white fibre, which speedily dries in the sun after it has been scraped. It is then known as Itzle, probably the old Aztec name. After the two men have collected about 40lbs., which they can do easily in a day, the fibre is carried to their huts, and in a few days taken to the factories to be made up into ballots and sent on mules' backs (two ballots weighing about 8 cwt.) to Tampico, a toilsome journey across the mountains of over 400 miles.

The best and longest fibre is obtained from young or virgin plants. Although the plant is not killed by the removal of the leaves, yet, after the first crop is taken away, the subsequent fibre is short and of bad colour.

Just before flowering the natives cut down the stem or flower stalk, peel it and eat it raw like sugar cane, or else roast it before eating. The plant produces a very pretty yellow flower. The flower-stem, before the fruit is ripe, is also cut in slices and fried in fat; when it makes a nice vegetable, and large quantities are thus eaten.

The plant is raised from seed, but grows also from shoots of the old plant. There are about 20 square miles of land here which formerly belonged to the Jesuits, but having been confiscated, now belongs to private owners, and this is covered with virgin plants. In other localities, the young plants being exhausted, only short and poor fibre is obtained. Some of the fibre is brought from Zacaticus and Tula.—*Arthur Robottom.*

THE FOOD OF PLANTS.

VEGETABLE extract, mucilage, and carbon, with water as a vehicle, constitute the principal food of plants presented to the roots under varying circumstances of soil and temperature which favour their assimilation, while atmospheric air, when of a suitable temperature and circulating freely amongst the trees, acts upon them through the leaves and the bark. The effects of stagnant air may be seen in cases where from want of a proper circulation and the exclusion of light the side branches die and drop off, leaving only a few green ones at the top, the tree increasing principally in length as these push up in quest of food.

Some writers have assigned to plants the power of selecting their food from the solids in the soil without the aid of water, while the opinions that water alone and even air alone are sufficient to secure plant growth have also been advanced. Pure water can only be obtained by distillation, as it does not exist in Nature unmixed with gaseous, saline, or earthy matters. These matters are carried into the leaves and the bark along with the water which is thence evaporated, leaving the substance behind. Whatever enters the plant, whether in the form of carbonic acid or as water and atmospheric air, becomes decomposed, after which some of its elements pass off, while others recombine in different proportions, forming gum, sugar, fecula, and azotic products.

A plant whose roots are placed in pure water will not flourish until carbonic acid is admitted. Carbon, of which the substance of plants so largely consists, can only enter the plant as carbonic acid gas, as may be proved by placing the roots in pounded carbon, and watering with distilled water, when no growth will take place. Nitrogen, or azote, contributes largely to the nutrition of plants, and its presence in the gluten and the vegetable albumen, as well as in the alkalies, shows that it is essential.

Silex is taken up by some plants in large quantities, and more especially by the grasses and the bamboo. It is stated that the skin, or covering, of the rattan palm contains so much of it that sparks are produced by striking this tree with a piece of steel. It is well known that silex is present in considerable quantities in the teak-tree, and also in the equiseta, or horse-tails.

Lime and the salts of lime—the sulphate and phosphate,—magnesia, sulphur, soda, potash, phosphorus, and metallic substances, are found in plants, soda being generally the most abundant. Even copper is found in the coffee-berry. The quantity of water passing through any plant which presents to the sun and the atmosphere a large evaporating surface, may be inferred from the experiments of Hales, who ascertained that a sunflower only three feet high lost twenty ounces of water daily.

The way in which the points of the roots push forward in to fresh soil as the old becomes exhausted of its nourishment, or turn aside and spread out in other directions when they meet with any impediment to their onward progress, even passing through small crevices and bursting asunder the stones by their powers of expansion, furnishes us with an instance of the wonderful provision made by Nature for the supply of the wants of the vegetable creation.

A perfect knowledge of the composition of plant-food would enable us to fertilise any soil which did not contain ingredients positively poisonous to plants. Root structures show that whatever enters them must be in a very minute state of sub-division; and chemistry proves that this comprises sulphates of lime and potash, vegetable extract, muriates of lime and soda, or common salt, and that, unless oxygen be present, both in the soil and the air by which they are surrounded, plants cannot vegetate.

In the February number of the *Journal of Forestry* is a short review of a valuable little pamphlet lately published at the request of the Scottish Horticultural Association, and written by Mr. W. Ivison Macadam, of Edinburgh. But, as is usual in such publications, the illustrations of the composition of plants are confined to farm crops. The sooner the services of such an analyst can be enlisted in the cause of arboriculture, the better for students of the science. As Mr. Macadam gives important information upon various points which have already been treated of, more discursively, in these papers, a summary of his tables of plant-food will supply me with an appropriate recapitulation.

The principal mineral ingredients in plants are nine in number. —potash, soda, lime, magnesia, iron, phosphoric, sulphuric and silicic acids, and chlorine.

Potash, containing the metal potassium (K), also present in nitre or saltpetre (KNO_3), in muriate of potassium, or chloride of potassium (KCl), and in kainit as sulphate along with the chloride of magnesium.

Soda, containing the metal sodium (Na), which also forms a part of common salt or chloride of sodium (NaCl), Glauber's salts or sulphate of soda ($Na_2 SO_4$), and nitrate of soda or cubical nitre ($Na NO_3$).

Lime, a compound of calcium (Ca), also existing in chalk or carbonate of lime ($CaCO_3$), and stucco, gypsum, or sulphate of lime (Ca SO), and in bone in combination with phosphoric acid as insoluble or bone phosphate ($Ca_3 2PO_2$).

Magnesia, containing magnesium (Mg), also found in Epsom salts, or sulphate of magnesium ($MgSO_4$), and as chloride of magnesium ($MgCl_2$) in kainit.

Oxide of iron, consisting of iron and oxygen.

Phosphoric Acid (PO_5). Its principal state of combination is with lime as bone phosphate ($Ca_3 2PO_4$), and as soluble phosphate ($Ca_2 PO_4$).

Sulphuric Acid (SO_3), found in combination with lime as stucco ($CaSO_4$), and forming the acid portion of Glauber's salts (Na_2SO_4).

Silica is made up of silicon and oxygen. It forms sands, and in combination with metals silicates.

Chlorine is a yellow-green gas, and is found as a part of common salt (Na Cl), muriate of potash (KCl), and chloride of magnesium ($MgCl_2$).

The organic constituents of plants are starch, sugar, dextrose, oil, gluten, legumin, cellulin, and lignin.

Starch ($C_6 H_{10} O_5$) softens in cold water and gives a semi-solution in hot.

Sugar ($C_{12}H_{22}O_{11}$) is found principally in the stems of plants, chiefly grasses, as the sugar-cane; and a few trees as the maple and date palm; and also in the tubers of beet and carrots.

Dextrose, or grape sugar ($C_6H_{12}O_6$), is another variety of sugar principally obtained from fruits. *Oil* is obtained from rape seed, the castor plant, and the cocoa-nut. *Gluten* is a white sticky substance obtained by washing flour in a cloth with water. It is abundant in cereals. *Legumin* is obtained from peas, beans, tares, &c. *Cellulin* composes the walls of the cells in plants. *Lignin* is a hard matter of woody fibre deposited in the cells.—*Journal of Forestry.*

MANURES—A SUBSTITUTE FOR PERUVIAN GUANO WANTED.

I SHALL now refer to what is acknowledged to be the backbone and sinew of the growth of every crop—that is manure. Twenty-seven years ago, during the heat of the Crimean War, when grain was at famine prices, the great cry was artificial manure—anything to raise up larger crops. Pervian guano was by that time well known and extensively used, but the great run on it raised the price so much, that in answer to the popular cry for some other and cheaper stimulant for the soil, manufactured chemical manures came to the front, the more readily that the guano deposits were seen to be wearing down, and the quality getting worse. Crushed bones and bone-meal had been in use, along with guano, many years previous to this, but dissolved bones, superphosphate, sulphate of ammonia, nitre of soda, and various other forms of nitrogenous and phosphatic compounds were added to the list of manures. In the infancy of such a gigantic trade, as might be expected, the dishonest and swindling element was not without its representation. No sooner had the trade gained a footing, than our markets were flooded with commission agents, each pretending to sell the best and cheapest mixture, warranted to force crops on any soil. At this time very few, I might almost add no farmer, thought of analyzing the manures he bought. It was a new trade to them; as a rule they knew nothing of the component parts of the various manures, or of their proper and economical application to the various soils and crops. A great many of them held their farms on pretty easy terms, having taken them during the period of agricultural depression immediately preceding the prosperous years of which I am speaking. They bought and applied their manures by rule of thumb. It did not seem to trouble them, so long as the results left a balance on the right side of the ledger. It was only after the lapse of several years, when that plague of the farmer—the manure commission agents—increased to such an extent, that at most of our markets they outnumbered even the farmers themselves. Then it began to dawn on their minds that there must be something radically wrong in a trade that could support such an army of sellers. It is now an ascertained fact that many special mixtures, which contained little or no manurial ingredient whatever, were sold at a clear profit to the vendor, of £6 or £7 a ton.—*Mr. Thomas Lawson in N. B. Agriculturist.*

NOTES ON SOME TREES YIELDING INDIA-RUBBER.

INDIA-RUBBER or Caoutchouc is afforded by a considerable number of trees and shrubs, chiefly, if not entirely, members of the families *Euphorbiaceæ*, *Artocarpaceæ*, and *Apocyneæ*. It is to be distinguished from gutta-percha, which is a product of trees belonging to the family *Sapotaceæ*.

In its natural condition in the plant caoutchouc is a milk-like fluid, and the channels in which it occurs occupy a definite position in the structures composing the stem. It is of the highest practical importance to bear in mind that the "milk-vessels" occur wholly in the bark, externally to the cambium-layer or vitally active part, of the stem where growth goes on. There are none in the wood, nor in the outer corky, papery, or green layers but only in the inner part of the bark, and either adjacent to or in its bast or liber-tissue.

The kinds of rubber-trees at present exciting interest in Ceylon are :—

1. *Ceará Rubber-tree.*—Manihot Glaziovii, *Müll. Arg.*
2. *Para Rubber-tree.*—Hevea Brasiliensis, *Müll. Arg.*
3. *Central American Rubber-tree.*—Castilloa Elastica, *Cerv.*

These three are all natives of tropical America, and are in cultivation at both Peradeniya and Henaratgoda gardens. The two former are North Brazilian Euphorbiaceous trees; the last is Artocarpaceous and extends over a wide area—from Mexico as far south as Guayaquil on the west coast of South America.

None of these species has been yet subjected to systematic cultivation out of a botanic garden, but the efforts of the Indian and Home Governments, extended over many years, have at length brought us to the eve of that long-desired result. It will therefore be well to make public what is known of the nature of these plants, of their surroundings in their native localities, and of the methods by which the product is obtained and prepared. Our information is unfortunately but scanty, being mainly derived from the somewhat meagre accounts of the few travellers who have had the opportunity of seeing the trees wild, and especially of the veteran Collector, Mr. R. Cross, employed by the Indian Government, by whose energy and perseverance they were brought to England.

From these extracts, and from the results of the cultivation of the trees at Peradeniya and Henaratgoda gardens, it is hoped that some answer to the numerous questions recently addressed to me by planters and others, may be given, and some guidance afforded towards a successful cultivation in Ceylon.

I.—Ceara Rubber.—*Manihot Glaziovii.*

1. *Locality, Soil, and Climate.*—Ceara is a coast town of Brazil in lat. 4° S., and the flat country which runs back to the hills is described by Mr. Cross as manifestly possessing "a very dry arid climate for a considerable part of the year. This is evident from the fact that mandiocca and other crops require to be irrigated. The rainy season is said to begin in November and end in May or June; torrents of rain are then reported to fall for several days in succession, after which the weather moderates for a brief space. According to some statements there are occasional years in which hardly any rain falls. The assertion concurs with the aspect presented by the country in general. The daily temperature on board the ship ranged from 82° to 85° F., but inland it is often, probably, 90°. The localities traversed by me nowhere seemed to be elevated more than 100 feet above the sea." At Pacatuba, about forty miles from Ceara, the actual place where the specimens were obtained, "the general forest was tolerably high, but the sparse small foliage did not afford much shade from the fierce rays of the sun. The soil was in places a sort of soft sandstone or gravel which was bound up in the most extraordinary manner. Neither grass nor weeds grew among this underwood, and there was an entire absence of ferns, mosses, and other plants." In another place, somewhat further from the coast, the traveller shortly after entering the bush-like forest "came on a large tract of land covered by immense masses of grey granite, some of which might be fifty tons or more in weight. These had been broken where they lay, and were the result of a volcanic explosion. Rounded masses of the same rock also cropped out in many places......................Many good-sized rubber-trees were growing in the spaces between these granite masses....................The situation was very dry, but no doubt some seedlings had sprung up, which, owing to numerous thickets of shrubs, were not perceived."

2. *Propagation and Planting.*—Mr. Cross's directions are as follows:—"Seeds are early produced, if the tree is not shaded. They should be buried in brown sand, kept pretty moist until there are indications of growth, when they may be planted out permanently. In some situations where the ground is rough and strong they might be sown broadcast. Meantime I would suggest the formation of plantations by cuttings, which will take root as easily as a willow. These should be taken from the points of strong shoots and may be one foot in length. In planting, each cutting may be put down in the soil to a depth of six inches. If scarce, the entire shoot may be cut into pieces, each possessing a bud, all of which will grow, if covered with half-an-inch or so of soil. On loose sandy soils, or exhausted coffee land, plantations may be formed at little expense. Hard, dry gravelly wastes, if found to support any kind of bush, are also suitable sites. Holes might be made in strong land with an iron jumper and a stout cutting put into each and filled with pebbles. On bare, or thinly covered portions of rock the cuttings might be laid down flat, and a little heap of stones or any kind of *débris*, about the size of a molehill, piled over each, care being taken that the extreme point of each cutting with a bud is left uncovered. I do not advocate planting in an entirely barren desert, but wherever there is any sort of stunted tree or scrub vegetation, with an occasional sprinkling from a monsoon shower, the tree is likely to prosper."

Experience of the plant in the botanic garden here has proved the general accuracy of the above remarks. There can be no doubt of the hardiness of the species, its readiness of culture, and adaptability to circumstances. It grows equally readily from seed or from cuttings, and though a native of a tropical sea-level, thrives well here in Ceylon up to at least a level of 3,000 feet, and on the most barren soils. It has succeeded equally in Calcutta and Madras, but the wet season appears to have killed it at Singapore. It would seem especially adapted for the dry and barren districts of our Eastern and Northern Provinces, or in the higher districts, but it would not be wise to risk it in localities where the temperature is liable to fall below 60° F.

Germination of Seed.—The seed coat is of remarkable thickness and very hard, and the natural process of germination occupies a long period—it is said more than a year. All that is necessary to hasten this, if desired, is to assist the seed coat in splitting. This is best effected by holding the seed firmly, and rasping off with a file both edges at the radicular end.* It is best not to file off the actual end, as it may thus easily happen that the radicle of the embryo may be injured. After this treatment, properly performed, the young plant appears above ground in two or three weeks. The seedlings require no particular attention. They grow rapidly and may be finally planted out at distances of twenty feet. A peculiarity which they share with their close relative the mandioc is the possession of large tubers on the spreading roots. The trees at Peradeniya, from which seed has been distributed to Burmah, India, Jamaica, &c., flowered at the age of eighteen months, and at the present time (at 2½ years) the larger ones form branching trees about 25 feet or 30 feet high, with a stem 1 foot 9 inches in circumference at a yard from the base, and a smooth, silvery birch-like bark readily peeling off; being about half the size of those which Mr. Cross describes, and which may be assumed to have been fully grown.

3.—*System of collecting the Rubber.*—I quote again from Mr. Cross's report:—"This is an operation of a very simple description. On commencing to work, the collector takes with him a stout knife and a handful of twigs to serve as a broom. Arriving at a tree, any loose stones or dust are swept from the ground around the base, and some large leaves are laid down to receive the droppings of milk which trickle down. Some do not go to the trouble of sweeping the ground or laying down leaves, for which reason the milk adheres to sand, dust, decayed leaves, and other impurities. The outer surface of the bark of the trunk is pared or sliced off to a height of four or five feet. The milk then exudes and runs down in many tortuous courses, some of it ultimately falling on the ground. After several days the juice becomes dry and solid, and is then pulled off in strings and rolled up in balls or put into bags in loose masses. Only a thin paring should be taken off, just deep enough to reach the milk vessels, but this is not always attended to. Nearly every tree has been cut through the bark, and a slice taken off the wood. Decay then proceeds rapidly, and many of the trunks are hollow. In this condition the trees must yield far less milk, and many no doubt are broken over by the wind, or wither away. Collecting is carried on during the dry season only, when rain seldom falls."

Mr. Cross says nothing as to the age of the trees so operated upon; probably the collectors treat all indiscriminately. In the sequel of his report, however, he incidentally remarks that Ceara rubber may be tapped on attaining "a diameter of four to five inches," which is the case here in Ceylon after about two years' growth. But unless there were a very large number of trees in an extensive plantation, this would certainly be labour thrown away. The tree, however, comes so early to maturity, as shewn by the production of seed, that it is improbable that it attains any very great size. The process above described must be, if thoroughly done, almost exhaustive of the milk, but in the case of a small stem it would be a work of some care and time to so conduct it as to avoid cutting into the wood, and probably some of the methods afterwards described will be preferred. But these are practical difficulties which it may be safely assumed the ingenuity of our planters will quickly master.

II.—Para Rubber.—*Hevea brasiliensis.*

1. *Locality, Soil, and Climate.*—The town of Para occupies a position near the mouth of one of the vast embouchures of the Amazons in about south latitude 1°, but the district of the same name extends over a vast forest region to the south and west, throughout which and the enormous forests of Central and Northern Brazil this and allied species are abundantly found. The climate has been often described and is remarkable for its uniformity of temperature, usually not exceeding 87° F. at midday or below 74° at night. The greatest heat recorded is 95°, and the mean for the year is 81°.

The rainfall occurs principally during the months from January to June, the maximum being in April when it reaches 15 inches. For the remaining six months of the year very little falls, but there are fine days in the wet season and occasional showers in the dry. The whole country is

* This end is to be recognised externally by possessing at its side a flat two-lobed appendage technically known as the car uncle.

covered with dense moist forests, and the soil near the numerous and gigantic rivers is deep, heavy, and very fertile. During the wet season much of the low-lying country near the Amazon's mouths is flooded. In the *Gapos* near Para, visited by Mr. Cross, he found a flat district only three or four feet above the highest tides and completely intersected with water-courses at low tide, filled with a soft rich mud. The forest here, in which caoutchouc collecting was vigorously carried on, was 80 or 100 feet high, and very damp and unhealthy, the soil full of moisture and very rich and fertile. The young plants, however, were not often observed to grow actually within the reach of the tides, but it is evident that they must frequently be subject to be partially covered with water.

2. *Propagation and Planting.*—This valuable species as yet has been propagated from cuttings only. No fresh seeds were brought to this country, but to judge from dry ones in the herbarium of the British Museum, London, they are considerably larger than those of the Ceara rubber. Our largest trees at Henaratgoda, three years old, are thirty feet in height with a slender stem scarcely branched, and about twelve inches in circumference near the base; but neither there nor in Peradeniya have they shown any symptoms of flowering.

Cuttings may be taken from the green lateral twigs as soon as they begin to harden; they strike readily in rich firm land. Mr. Cross observes that "for planting on inundated lands the period of high flood should be preferred. Cuttings of greater length would be required in this case, the lower ends of which should be sliced off in the form of a wedge. The workman could take a bundle of these, and wading into the water would plant at proper distances, but perfectly upright, taking care to push each cutting down deep enough in the soft muddy bottom, so that not more than three or four inches is above the surface of the water. The same rule would be applicable when planting in sludge or soft marsh land. The crowns of the cuttings must not, if possible, be put under water, as the young growths springing therefrom might rot. Seeds will not be found very applicable for planting in watery places or deep mud deposits. Some would come up, but a good many would mould and decay. In the varied course of circumstances and conditions, slight changes and modifications in the methods of working will no doubt suggest themselves ....It should be planted in places where nothing else could be profitably cultivated, such as frequently inundated river margins, marsh land, and mud deposits." It would not be desirable to form a plantation in any locality where the temperature at any time falls to 60° F.

The tree when fully grown does not exceed a height of about sixty feet, and the largest trunk measured by Mr. Cross was six feet ten inches in circumference at a yard from the ground. From the upright habit of the tree it will not be necessary to plant at any great distance apart.

Over 500 plants have been sent from Ceylon to Burmah and some to the Madras Presidency. An attempt to grow the tree in Assam failed.

3. *Collection of the Rubber.*—Several accounts have been given of this, the fullest and most recent being that of Mr. Cross, who saw in practice the methods employed in the neighbourhood of Para. His description is as follows:—

"The collectors begin to work immediately at daybreak, or as soon as they can see to move about among the trees. They say the milk flows more freely and in greater quantity at early morn. I do not attach much importance to this statement, but I have recorded it. Another and more probable reason is, that as rain often falls about two or three o'clock in the afternoon, the tapping must be done early, as in the event of a shower the milk would be spattered about and lost. The collector, first of all, at the beginning of the dry season, goes round and lays down at the base of each tree a certain number of small cups of burnt clay. At the lesser trees only three or four are put, but at the larger ones from eight to twelve are deposited. The footpaths leading from tree to tree are likewise cleared of sapling growths, and the bridges over the *gapos* [natural ditches] formed at each place by the trunk of a tree are, where necessary, replaced. On proceeding to his work the collector takes with him a small axe for tapping, and a wicker basket containing a good-sized ball of well-wrought clay. He usually has likewise a bag for the waste droppings of rubber, and for what may adhere to the bottoms of the cups. These promiscuous gatherings are termed *sernamby*, and form the "Negro head" of the English market. The cups, as already stated, are of burnt clay, and are sometimes round, but more frequently flat or slightly concave on one side, so as to stick easily when with a small portion of clay they are pressed against the trunk of the tree. The contents of fifteen cups make one English imperial pint. Arriving at a tree, the collector takes the axe in his right hand, and, striking in an upward direction as high as he can reach, makes a deep upward sloping cut across the trunk, which always goes through the bark and penetrates an inch or more into the wood. The cut is an inch in breadth. Frequently a small portion of bark breaks off from the upper side, and occasionally a thin splinter of wood is also raised. Quickly stooping down he takes a cup, and pasting on a small quantity of clay on the flat side, presses it to the trunk close beneath the cut. By this time the milk, which is of dazzling whiteness, is beginning to exude, so that if requisite he so smooths the clay that it may trickle direct into the cup. At a distance of four or five inches, but at the same height, another cup is luted on, and so the process is continued until a row of cups encircle the tree at a height of about six feet from the ground. Tree after tree is treated in like manner, until the tapping required for the day is finished. This work should be concluded by nine or ten o'clock in the morning, because the milk continues to exude slowly from the cuts for three hours or perhaps longer. I may state that there is a great difference among collectors in the performance of these duties. Some take care to get good clay previously, and incorporate it well, so that a very small portion is needed to lute the cups to the trunks; they also work with neatness and intelligence, and invariably collect a good quantity of milk. Others, again, do not take the trouble to prepare clay beforehand, but merely scrape up a handful when they require it at the side of a *gapo*, which is often of little consistence, so that a large quantity is required to fasten the cups. This class of collectors have often many fragments of clay or other impurities in their milk, the result of not following a proper method of working. The quantity of milk that flows from each cut varies, but if the tree is large and has not been much tapped, the majority of the cups will be more than half full, and occasionally a few may be filled to the brim. But if the tree is much gnarled from tapping, whether it grows in the rich sludge of the *gapo* or dry land, many of the cups will be found to contain only about a tablespoonful of milk, and sometimes hardly that. On the following morning the operation is performed in the same way, only that the cuts or gashes, beneath which the cups are placed, are made from six to eight inches lower down the trunks than those of the previous day. Thus, each day brings the cups gradually lower until the ground is reached. The collector then begins as high as he can reach, and descends as before, taking care, however, to make his cuts in separate places from those previously made. If the yield of milk from a tree is great, two rows of cups are put on at once, the one as high as can be reached, and the other at the surface of the ground, and in the course of working, the upper row descending daily six or eight inches, while the lower one ascends the same distance, both rows in a few days come together. When the produce of milk diminishes in long wrought trees, two or three cups are put on various parts of the trunk, where the bark is thickest. Although many of the trees of this class are large, the quantity of milk obtained is surprisingly little. This state of things is not the result of over-tapping, as some have stated. Indeed, I do not believe it is possible to overtap a tree if in the operation the wood is not left bare or injured. But at every stroke the collector's axe enters the wood and the energies of the tree are required in forming new layers to cover those numerous wounds. The best milk-yielding tree I examined had the marks of twelve rows of cups which had already been put on this season. The rows were only six inches apart, and in each row there were six cups, so that the total number of wood cuts within the space of three months amounted to seventy-two. It grew close to a *gapo* only eight inches above high-tide mark, and being a vigorous tree the cups were usually well filled, but with two years or so of such treatment the tree would probably be permanently injured. It has been supposed that the quality of the milk is better in the dry season than during the rains. Such is the case with some vegetable products, but as regards India-rubber there ought not, I think, to be any appreciable difference. In the rainy season the milk probably contains a greater proportion of water, but, on the other hand, I am of opinion that then a larger quantity of milk flows from the tree. No doubt the dry season is the most suitable for caoutchouc collecting, although, wherever a plantation is formed with preparing house, convenient tapping may certainly be always carried on when the weather is fine. . . . There are two other methods adopted in tapping, which are chiefly confined to the upper Amazon and tributaries. Both are exactly on the same principle, the materials used being only a little different. The loose outside bark of the tree is cleaned off to a height of about three feet. Beneath, a gutter or raised border of clay is pasted or luted to the trunk, enclosing one-half of the entire circumference. Cuts are thickly made in the bark above this, from which the milk flows down to the gutter, whence it is conveyed to fall into a calabash conveniently placed. The other mode is by winding round the trunk the stout flexible stem of a climber, and claying it round securely so that no milk may escape between the trunk and the climber. These plans are not extensively adopted, and can only be successfully put in practice where the trees have not been previously tapped. There is always a great deal of "negrohead," the result of the distance the milk has to run, and to the large quantity of clay employed in the process.

4. *Collection of the Milk.*—"Going from tree to tree at a sort of running pace the collector empties the contents of the cups into a large calabash, which he carries in his hand. As he pours the milk out of each cup he draws his thumb or forefinger over the bottom to clean out some which otherwise would adhere. Indeed, a small quantity does remain, which is afterwards pulled off and classed as *sernamby*. The cups on being emptied are laid in a little heap at the base of each tree, to be ready for the following morning. The trees occur at various distances from 10 to 100 yards apart, and as I travelled over the intricate network of muddy footpaths, I continually felt perplexed and surprised that the natives have not yet seen the advantages that would be derived by forming plantations, whereby more than twice the quantity of caoutchouc might be collected in one-fourth the time, and at far less cost and labour."

The trees are tapped if they have a circumference of eighteen or twenty-four inches, and the rough process above described is carried on for many years, until the constant and extensive injury to the young wood causes their death, for some years previous to which event they almost cease to yield milk and are practically abandoned.

I will be advisable, in order to avoid this injury, to employ an instrument for cutting so shaped and guarded that it shall not be able to penetrate

beneath the inner bark. With this precaution it will probably be found unnecessary to rest the trees as has been recommended by some; but actual experience alone can decide on the method of tapping which will secure the greatest yield with the least damage to the trees' general vitality.

III.—Central American Rubber-Tree.—*Castilloa elastica.*

1. *Locality, Soil, and Climate.*—The very extensive geographical range of this tree shews it capable of existing under considerable varied climatic conditions. The forests in which it grows are usually at or near sea-level, but it has been observed at an elevation of 1,500 feet on the Pacific coast. The soil varies, but the plant avoids marshy or boggy land, appearing to prefer warm deep loam or sandy clay, and especially affecting the margins of small running streams where it grows in little groups. A dry or a rainy climate seems equally suitable, but a high and equable temperature, which does not sink below 60° F. at any time, is essential.

2. *Propagation and Growth.*—This is a very much larger tree than those above described, being, when fully grown, of the imposing height of 160 to 180 feet, with a stem of 12 to 15 feet in circumference. It grows very rapidly. At Henaratgoda at two years of age it was 23 feet in height. The bark is thick, and the wood soft and readily decaying. We received but a few plants of this species in Ceylon, and have had little experience in its management. No flowers have been yet produced, and Dr. Thwaites did not find cuttings of the ordinary kind to succeed well. We are now, however, endeavouring to propagate at Peradeniya by various other methods.

Mr. Cross has the following remarks:—"Trees in good situations will produce seeds early, but these will require to be planted without delay, as drying destroys their vitality." The tree is stated to flower in January, and the fruit to be ripe in April. "Stout branches, cut into pieces, each possessing a bud and covered lightly with soil, will generally be found to grow. Strong cuttings a foot in length and furnished with buds, when planted in the usual way, will become strong plants sooner. However, the propagation of this tree will not be found so easy as the Ceara rubber. In the planting out of young plants, the petiole or leaf-stalk of the lowest or oldest leaf should be buried in the soil. By following this simple rule the plant commences to grow at once, its growth is vigorous, and the trunk symmetrical. But if at the period of planting there is much bare stem above ground, then growth is usually slow, the plant remains 'leggy' for some time afterwards and never makes a good tree." The plant has a curious habit of dropping its young branches, which disarticulate by a regular joint, like deciduous leaves, and leave a clean scar on the surface of the stem. From what has been said above as to its native sites, it would seem that our south-western coast would present many favourable localities for this valuable tree.

3. *Collection of the Rubber.*—Milk is abundant and flows readily, but it is of a somewhat more watery consistence than that of the Para rubber. In consequence of the large size of the trees it is the practice of the collectors in Panama and other parts to cut them down. A groove or ring is first cut round the base of the trunk and the milk received into large leaves. "The tree is then felled, and rings or channels are cut out around the prostate trunk at about twelve or fourteen inches apart," and the rubber allowed to run into leaves or vessels. In Nicaragua the trees are tapped with sharp axes in various ways, and the trees so much injured that the process is performed at intervals of three years. The milk is received into iron pails. It does not appear that this species is tapped until it has a diameter of sixteen or eighteen inches, which Mr. Cross thinks might be attained in six years.

In conclusion, a few words may be said about the preparation required to fit caoutchouc for the market. It is clear that mere exposure to the air is sufficient in some cases to effect the coagulation of the milk into a solid mass. This is all the preparation apparently that the Ceara rubber receives, which comes into the market in bales consisting of the rolled up strings pulled off the tree. But it seems that a decomposition is liable to occur in the milk if exposed in any quantity, and it is usually desirable to reduce it to a solid mass as quickly as possible. For this purpose the cautious application of dry heat is the best; the best Para rubber is prepared by being poured over a flat paddle-shaped mould, which is held in the thick hot smoke from burning wood and palm-nuts till it solidifies, then slit down one side, the mould taken out and the "biscuit" hung up to dry. In several parts of Central America coalescence is effected by the addition to the milk of the juice of certain plants (especially of *Calonyction speciosum*, which is a common convolvulus here in Ceylon.) This causes the separation of the caoutchouc, which floats in the liquid like a mass of soft cheese, and has to be pressed and rolled to get rid of the fluid still remaining in its substance.

Probably carefully conducted evaporation in shallow pans by artificially regulated heat would be found an effective method.

The purity of the prepared rubber being a matter of first importance, all pieces of bark and earth should be removed by passing the milk through sieves. Small pieces or thin sheets of caoutchouc are preferred to large masses in the market from the facility of estimating the purity of the article.

Absolute dryness of the rubber is also a point requiring the greatest attention, and may require hydraulic pressure for its thorough attainment.

As much as 129,163 cwts of caoutchouc were imported into England in 1874, of which 70,866 cwts was American and obtained from the plants here under consideration. The value of this latter was £1,007,416. The demand for the best sorts is constantly increasing. On the relative market values of the various kinds of India-rubber, reference may be made to the excellent "Report on the Caoutchouc of Commerce" by Mr. Collins, and printed for the Indian Government in 1872, to which I am indebted for some of the above information, and to a paper by Mr. C. R. Markham in the *Journal of the Society of Arts* for April 7th, 1876.

I may be permitted to add that it is gratifying to reflect on the prominent share which the Royal Botanic Garden at Peradeniya, under the care of my distinguished predecessor, Dr. Thwaites (as detailed in his Reports from 1875-1878), has taken in the acclimatization of these valuable trees of the western hemisphere in Burmah and India; where, as well as in Ceylon, it may be confidently expected that they will become a valuable source of revenue.—*Ceylon Observer.*

HENRY TRIMEN, Director.

Royal Botanic Gardens, Peradeniya.
29th March 1880.

THE DRAWBACKS TO INDIAN AGRICULTURE.

MR. ROBERTSON'S paper on Agriculture in the Madras Presidency, to which we called attention the other day, contains so much of value, and records so many important facts, that we need make no apology for dealing more at length with the matters which are therein dealt with. Mr. Robertson's previous report on Coimbatore was published as a parliamentary paper at the instance of Sir George Balfour. This account was no sooner issued than attempts were made to challenge the correctness of its conclusions. They were but too sadly verified later, and now the writer extends his survey over the whole presidency. Madras is the poorest of the Indian presidencies, and has always in some sort been looked down upon by the other two. Circumstances have of late directed more attention to the state of affairs there, and the great famine and the Rumpa rebellion would together suffice to fix our minds on the need for reform. The first point to which Mr. Robertson draws attention is the admitted fact of denudation coupled with the extension of the agricultural area. The result of this sweeping away of the jungle and what remains of forest is most injurious; and Mr. Robertson is in favour of what Mr. Robert Elliot and others have so long championed—an increased plantation of trees on hill and plain alike. As it is, the rivers are much more subject to floods than they were, and the rain-water, not being retained, rushes away. Still more important, however, than this, which can only be gradually remedied, is our present method of raising rent. Not only does it cost 22 per cent. to get in the land revenue of Madras, whereas in England for all agency-charges 5 per cent. is considered sufficient, but our present system tends to encourage bad farming and to discourage good. This has frequently been urged by outsiders, and the public still awaits with interest and anxiety Mr. Caird's report on this question. But here we have the statement as plainly as can be. "Under the rent settlement now in force a premium is offered for bad farming." That surely is a very grave observation to come from an official of experience. Yet though it is of the very highest importance to the State that the land should be well farmed, no steps are taken towards improvement. Moreover, the officials whose percentage on collection is this large proportion of nearly one-fourth, are unversed in agriculture, and are consequently unable to make suggestions of any value to the ryot. It is only fair to say here that some authorities hold that the best thing is to let the ryot alone when he has the means of getting water or can be instructed how to obtain manure. There is every reason however why Mr. Robertson's suggestion that one portion of a civilian's necessary knowledge should be agriculture ought to be adopted. It is, indeed, absurd that acquaintance with Greek plays and French literature should rank above an acquaintance with agriculture when we consider what duties the collectors and their subordinates have to perform. The poverty of the unirrigated land now being farmed in Madras is extreme. Much of it does not yield more than six or seven bushels of inferior grain an acre. Especially the land lately brought under cultivation is of a miserable character, and the restricted area now available—owing, as is stated, to the pressure of propulation on the means of subsistence—not only renders fallowing impossible, but deprives the people of the manure which they used to obtain from their cattle depastured in the waste. Thus, according to Mr. Robertson, we have a process of desiccation going on consequent on the removal of timber and jungle; we have a gradual resort to less and less fertile soils, with less and less manure applied to them; while, above all, there is a system of exacting land tax which, besides being costly, directly tends to discourage improvement.

But there is another point which is as important as any of these. Crops are divided into exhaustive crops, restorative crops, and fallow. Now in Great Britain the proportions of these are respectively—exhaustive crops, 55 per cent. restorative crops, 42 per cent.; and fallow, 3 per cent.; and this country possesses large tracts of permanent pasture which do not exist in India. Moreover, in England manures are used to a large extent. Now look at the proportions in Madras; exhaustive crops, 75 per cent; restorative crops 4 per cent; waste 21 per cent. "At present not 5 per cent. of the arable land is adequately manured." Yet, as we see, the croping is very exhausting; the crops are, of course, in such circumstances very precarious, and even the refuse matter does not find its way back to the soil. Can we wonder that, this being so, the ryots state that unirrigated soils are much less productive than they were? Experienced men, says Mr. Robertson, positively assert that the deterioration during the last thirty years has been not less than 30 per cent. At this rate what may we not look for as the result of this continual exhaustion? Is it not clear that each successive year, with an increasing population and deteriorating soil, the prospect of famine becomes more and more serious? Mr. Robertson makes a few suggestions, in themselves worthy

of more space than we can afford to give to them, for remedying this state of things. Of the tree-planting we have spoken. This will scarcely be brought about unless the Government exercises some pressure or offers some bonus. In his experiments with ploughs, Mr. Robertson found that in every respect the native plough is inefficient. Its draught is far heavier than the modern plough, it does not do the work nearly so well, and has to go over the same ground a number of times to produce a given result. The statistics of this point are curious and interesting, and it would certainly appear that the English plough in a more or less modified shape ought to be introduced. A society that would sell ploughs on, say the three or five years' system to these poor cultivators could scarcely fail to do good service. Of wells so much cannot be said. Raising water from a well when it is sunk is an expensive business in itself, and though this expense consists in the labour of the ryot and his bullocks, the result to him is really the same. Besides, the sinking of a well is a costly as well as a speculative business, and must be left to the judgment of the proprietor. Advances made for this purpose are not advisable as a rule. In the way of increased use of manure more might be done; for though there is not much manure—not perhaps more than sufficient to deal with 20 per cent. of the arable land—it would be easy to apply a large quantity beneficially. This is a matter which might very well be considered, inasmuch as organic measures not only increase the fertility of the soil, but retain moisture, thus neutralizing the effect of draught. But the first and main thing is to change the method of collecting the revenue, and to do away with a system which actually empowers the State to imprison a man for debt, and yet—the poor fellow's family being reduced to destitution for want of his labour—does not permit this punishment to wipe out his liability. Evidently the whole revenue arrangements in Madras need a thorough overhaul, as there is but too much ground for the belief that apart from the method of collection, and the harshness with which arrears are pressed for, the assessments in many districts are calculated on a wrong basis. The new Ministry will have serious work to do in India.—*Pall Mall Gazette.*

AGRICULTURAL AND HORTICULTURAL SOCIETY OF INDIA.

The usual Monthly General Meeting was held on Thursday, the 20th May 1880.

THE HON'BLE LOUIS S. JACKSON, C.I.E.,

President, in the Chair.

THE proceedings of the last Meeting were read and confirmed.

The following gentlemen were elected Members :—

Major J. Listen, Lieut. A. Connell, Messrs. J. J. Cumming, Philips White, W.A. Court Beadon, Andrew Ker, and Manager of the Rampore Tea Garden, Cachar.

The names of the following gentlemen were submitted for Membership :—

Baboo Jodrolaul Mullick,—proposed by Rajah Suttyanund Ghosal Bahadoor, seconded by Baboo Peary Chand Mittra.

Baboo Bejoy Kissen Mookerjee,—proposed by Baboo P. C. Mittra,—seconded by Rajah S. A. Ghosal.

Henry M. Lennox, Esq., Hyab, Nowgong, Assam,—proposed by the Secretary, seconded by Mr. W. H. Cogswell.

Baboo Kisserelal Gossain, Serampore,—proposed by Rajah S. A. Ghosal, seconded by Baboo P. C. Mittra.

William Oldham, Esq., C.S., Dumka,—proposed by Mr. H. M. Kisch, C.S., seconded by the Secretary.

Baboo Mohis Chunder Chowdry, Pleader, High Court,—proposed by Baboo P. C. Mittra, seconded by Rajah S. A. Ghosal.

Baboo Bholanath Dhur, Merchant, Calcutta,—proposed by Baboo P. C. Mittra, seconded by Rajah S. A. Ghosal.

Rejoined—J. Deveria, Esq., Calcutta, and G. E. Porter, Esq., C.S., Gya.

CONTRIBUTIONS.

A collection of seeds and plants, including *Araucaria Cookii* and Crotons of sorts; also seeds of *Gmelina Leichlardtii* and *Tristania conferta*, both good timber trees. From L. A. Bernays, Esq., V.P., Queensland Acclimatisation Society.

Seeds of several kinds of Eucalyptus. From Mr. C. F. Creswell of Melbourne.

Seeds of *Amherstia nobilis*, teak and "Padouk" (*Pterocarpus dalbergioides*). From C. Ady, Esq.

A few seedlings of *Amherstia nobilis*. From R. Rowett, Esq.

Tubers of Begonias, Achimines and Gesneras. From Dr. T. Beaumont.

Plants of *Cyrtodeira fulgida*. From Dr. G. King.

Seed of the blood-red Orange of Malta. From Col. W. M. Lees.

Seed and plants from the Nicobars. From E. H. Man, Esq.

A quantity of American Tobacco seeds of three kinds—White Stem, Orinoco, and Connecticut. From the Department of Agriculture, N.-W. Provinces.

RESIGNATION OF THE PRESIDENT.

Read a letter from the Hon'ble Mr. Justice Jackson, C.I.E., to the Council, intimating his resignation of the office of President of the Society, consequent on his approaching departure from India.

Submitted the following Resolution of the Council :—

"The Council cannot accept the resignation by the Hon'ble Mr. Justice Jackson, C.I.E., of the office of President, without placing on record their warm appreciation of the interest he has taken, and the valuable services he has rendered to the Society in dealing with the various subjects that have been under consideration since he was unanimously elected in January 1876. The Council regret exceedingly that ill health obliges Mr. Jackson to vacate office, and beg to propose in recognition of those services his nomination as an Honorary Member of the Society."

Baboo Peary Chand Mittra, V.P., in proposing the cordial confirmation of the above Resolution spoke to the following effect :—You are well aware, Gentlemen, that we are deeply indebted to Mr. Justice Jackson, our President, for the warm interest he has taken in the affairs of our Society, for the sound judgment he has brought to bear on the important questions which have come before the Council and the Society for consideration, and for his powerful advocacy and influential aid in improving the financial position of the Society. For these valuable services, Mr. Jackson is certainly entitled to our gratitude, and it is with much regret we now part. In bidding him farewell, let us hope that in returning to his native land Mr. Jackson may, by the blessing of God, be restored to the enjoyment of health and strength.

Mr. W. H. Cogswell, V.P., said, he had pleasure in supporting the Proposer's views, which were so ably expressed, and which so well coincided with his own opinions and feelings, and he was sure, those of the Council at large. The resignation of the President, Mr. Justice Jackson, would be a great loss to the Secretary, and a matter of very considerable regret to all, particularly under the circumstances that failing health necessitated such a step; and he could only hope that Mr. Jackson would be speedily restored to health by the change he was now contemplating.

The Resolution was then put and carried unanimously.

Mr. Jackson replied as follows :—

GENTLEMEN,—I am touched by the kindly terms used in speaking of me by the Proposer and Seconder of this Resolution; the more so, because I have always regarded myself as a mere stop-gap in holding office as your President, being well aware of the serious difficulties under which I labour. I can, at all events, claim the merit of having brought good-will to the aid of any qualities I may possess, and I can most truly say that, while the success of a President's administration must depend largely in the aid afforded by his colleagues in Council, I have had that assistance in the fullest degree, and it is to that assistance that I ascribe any advantage which the Society may have derived from my connection with it.

Gentlemen, the interruption of my official connection with the Society breaks one of the linked associations which have so largely entered into my later life in India. I am glad to feel that among the many friends whom I leave behind, I may count the Members of this Council, and it is particularly pleasing that in consequence of your flattering Resolution, the connection between us will not be altogether broken.

GARDEN.

The Head Gardener's Monthly Report was read, of which the following are extracts :—

"The weather during the past two months has been favourable for the Garden generally, alternating showers and sunshine. The work, has been as usual in regard to cleaning up the Garden. Preparations are being made for grafting work. Rose layering has been already put in hand; beds are being made around the centre lawn for the reception of roses received from Allahabad, Agra, and Lahore. We have, in the first instance, measured out one acre of land for experimental work in compliance with the Resolution of the Government of India (Agricultural Department) under date 27th February, 1880, but we shall not be able to carry it out this year in full integrity, the proposal having been made so late. The land (1 acre) having been marked out, it remains to decide what manures can be used, also the most appropriate crops to illustrate the action of the manures. Of the following, plants, we have a large stock in hand for distribution in the ensuing rains—*Licistona mauritiana, Caryota sobolifera, Vanilla aromatica, Licuala peltata, Casuarina muricata, Antigonon leptopus, Quisqualis Indica, Pandanus Mellori, Pothos, Caladium, &c. &c.*"

Mr. Gesson next refers to several presentations (already alluded to under the head of contributions), including a gift from Mr. C. Brown of some 200 Orchids, and a few Ferns collected at Port Blair; also some Palm seeds from the Royal Botanic Garden, Mauritius, which are valuable, as the seeds invariably germinate, and 50 seeds of *Amherstia nobilis* from Mr. C. Ady, of Moulmein. These have all unfortunately, failed; the cotyledons seemed to have separated from each other, exposing the delicate embryo at the base, this may account for their non-germination; seeds when sent should, if possible, be packed in some light material, such as a small plantain stalk folded double, a small quantity of brown paper would exclude the direct influence of the dry air. *Clianthus Dampierii* (of which some seeds have been recently received) has been tried several times in the Garden but have failed to germinate their success, depending apparently more on the soil than the climate. A nice collection of Gesneras, Archimenes, and Begonias have been received from Dr. T. Beaumont of Indore.

EXPERIMENTS WITH MANURES.

A preliminary report was read from the Sub-Committee appointed at last Meeting. The Committee submit a sketch-plan, suggesting certain kinds of manures and certain kinds of crops, to be carried out as far as practicable, but perference to be given to natural (farm yard) manures. That one acre of land be set apart for the purpose in the Society's garden that the manures employed be dried cow-dung, ashes of cow-dung, and cattle-box dung, and that a quarter of an acre be given to each, and one quarter be left unmanured. The test crops to be maize, sunn-hemp, jute, and bajra. Agreed to.

MODELS OF VEGETABLES PREPARED BY MESSRS. SUTTON OF READING.

The Secretary next drew the attention of the Meeting to the interesting large case of models of Vegetables presented to the Society, by Messrs. Sutton of Reading, and read the following extract of a letter from that Firm in reference thereto :—

"Mr. Jennings, when he was here, was very interested in our modelling-room, and in answer to our inquiry, whether he thought a present of a set of English vegetables would be acceptable to your Society, said, he was quite sure such a gift would be much appreciated.

"All these models are made by our own people on our establishment, from specimens grown in our trial grounds and elsewhere.

"We have only sent a few varieties, which are capable of cultivation in India. We hope by careful attention to the instructions enclosed in the box, it will not be found difficult to place them in the case on arrival."

The case in question (with a glass cover), measuring 7 feet by 3 feet, contains some 40 kinds of vegetables, exceedingly well modelled. All reached in excellent condition, without the least breakage, having been so carefully packed. The contents were much admired, and the cordial thanks of the Society were voted to Messrs. Sutton for this handsome and acceptable contribution to the Museum.

MODEL OF A SUGAR-CANE MILL.

The Secretary also drew attention to a contribution to the Museum from Messrs. Thomson and Myine, of Beheea of a model (half size) of their sugar-cane mill. The donors state that "there are now 9,500 of these mills at work in this and neighbouring districts and other parts of India, including 271 at Bunnoo, Trans-Indus. In the box you will find instructions as to the management of the mill in English, Oordoo, Hindee, and Bengalee, and also in these languages comparisons shewing the advantage worked out by the Beheea mill over the several native mills."

TURNIPS RAISED AT RAMOOLLAH.

Mr. W. H. Llewhellin submits several turnips raised from "Sutton's prize Swede," as specimens of the result of a recent trial on his grounds at Ramoollah, Sarun. The quantity realised was 880 maunds per beegah of 3,600 square yards, which is equal to about 40 tons per English acre. The ground these turnips were grown on was manured with "seetee" or indigo refuse. The Secretary, in connection with this experiment, called attention to several trials, with turnips, as introduced in Lawson's Agriculturist's Manual, especially to one of the most favourable, namely, a crop of Sweedish turnip, manured with bone-dust, which yielded only 27 tons per acre. The turnips sent down by Mr. Llewhellin are of excellent quality.

DISTRIBUTION OF USEFUL SEEDS.

The Secretary announced the receipt, since the last Meeting, of a supply of seeds of Guango (*Pithecolobium saman*), from the Royal Botanic Garden, Ceylon, of *Catalpa bignonioides* from the Society's seedsman at Philadelphia, and of *Reana* (*Euchlæna*) *luxurians* from the Society's garden. These are being widely distributed, and there is still a good supply remaining for applicants. The "Guango" is known as the Rain tree (a good fodder for cattle) and the Catalpa as an excellent Timber tree. Mr. J. H. Bridgman of Goruckpore, acknowledging receipt of the latter, observes :—"I think it probable that my neighbour, Mr. Peppé of Birdpore, would much like some of the seed ; and I should be very glad to send some to my friend, Mr. Cooke, of the Civil Service, who has lately been appointed to the management, under the Court of Wards, of the large estate of Awa in the district of Etah. He writes to me that he is applying himself zealously to arboriculture in that estate, and I am sure he would be very glad to have the opportunity of trying whether so valuable a tree as this Catalpa is said to be, can be successfully propagated."

Mr. W. G. Jackson, C.S., writing from Mirzapore, remarks—"It may perhaps interest you to know that I sowed the Reana last year both in the public gardens in Prome and in my own grounds. The soil was the ordinary soil of the place, and no manuring or irrigation was attempted. The plants all germinated and were transplanted without loss and flourished amazingly ; growing seven or eight feet high and seeding freely. My horses ate the plants with avidity. I do not think, however, that the plant is needed in Burmah. There is such an abundance of natural fodder trees that no fodder plants are ever cultivated. I do not ask for any this year, as the Manager of the Kuntil estate here has already introduced it. The fact that the seeds are not suitable for human consumption, is a very serious defect in native eyes."

COMMUNICATIONS ON VARIOUS SUBJECTS.

1. From Dr. John Macgregor, Superintendent Central Prisons, Benares, forwarding a plough for trial.

2. From Mr. W. Crawley ; Government Experimental Farm, Cawnpore, sending a plough for trial

3. From Messrs. Octavius, Steel & Co., sending, for identification, a few specimens of a destructive crysalis which has lately appeared in tea gardens in Cachar.

4. From Messrs. Begg, Dunlop and Co., forwarding specimen of an insect which is damaging the tea bushes in one of their gardens in Cachar

Mr. Wood-Mason, of the Indian Museum, gives the names of the insect above referred to, but is at present unable to suggest any means of destroying them.

5. From W. Aitchison, Esq., of Dooloo, Cachar, regarding the Carob tree and the Vanilla plant:—

"In the last publication of the Society's Journal, Vol. VI., Part II., New Series, I have read an interesting article on the Carob tree. It seems to be a most valuable as well as a very ornamental tree, and I think it would be well worth the trouble of trying to grow it in this district. I therefore beg leave to request your assistance in procuring some seeds ; and, as grafted trees seem to be the most reliable for giving good fruit, if you could also get me some grafted seedlings, I would be very much obliged. I will gladly pay all expenses in connection with procuring and forwarding of the seeds and seedlings.

"It may be of some interest to you to know that the young plant of Vanilla, which I received from you in January 1877, has thriven well, and is now in flower. As yet there are only two racemes or spikes of flowers showing, but even this much is some satisfaction. I planted this Vanilla in the rains of 1877 against a Jack-tree, and it has now run up fully twenty feet high. I have also taken four cuttings from it and had them planted against other Jack-trees, which seem to suit the plant very well, although, no doubt, it would grow equally well on several other kinds of trees. Mangoes, I believe, would suit well ; but the Jack is the only tree I have conveniently near."

6. From the Maharanee Surnomoyee of Cossimbazaar, presenting a donation of Rs. 100 to the fund, of the Society, with the expression of her good-will towards the labours of the Institution.

The cordial thanks of the Society were voted to the Maharanee for her kind consideration.

7. From Mr. C. F. Creswell, of Melbourne, presenting several kinds of Eucalyptus seeds and giving some useful information regarding their quality.

8. From P. de L. Lennox, Esq., Kangra, in allusion to a form of cattle disease prevalent in the Kangra district, and his mode of remedy.

9. From Mr. Warren Sterling, some remarks relative to the foot and mouth disease in cattle, and remedy for the same.

The three last papers were transferred for publication in the journal.

MINERALOGY.

PROFESSOR REDWOOD, Chemist to the London Petroleum Association, represents that the crude petroleum obtained from the wells in the Eastern Borongo island requires only one distillation to produce 64 per cent. of refined burning oil equal in quality to American or Canadian productions.

THE Bombay papers announce that Mr. C. Millett Thomas, a mining engineer well-known in England, has, associated with Captain Archer, arrived in India with the view of opening up mining works here. A powerful syndicate has been formed in England, under the name of the Foreign and Colonial Mining Exploring Company, the object of which is sufficiently explained in name. Mr. Thomas has come to India as the representative of that company; and is about to visit and report on those mineral fields that may offer promising prospects. We are told that he will take a greater interest in copper and lead deposits than in gold. This is a promising feature in his plan of works ; for attention has of late been so much attracted to the Indian gold fields, that the presence of the more useful minerals in this country appears to have been lost sight of.

THE memorandum on the right of the State to minerals is an interesting document, but will not, we fear, give much satisfaction. The only conditions sought at present to be attached to leases of land for mining purposes are in themselves reasonable enough, but the great fault they possess is their uncertainty. The Government of India in its communication to the Secretary of State for India says :—"But we consider that for the present, while the industry is undeveloped, an object should be to make the terms of mining leases of Government lands as simple and liberal as possible." This is all very well, but it seems to imply that, once the industry is developed, these terms will be multiplied and increased. And we have the greatest fear that this will be the result. The Government is wise in its generation, and does not wish to choke the industry in its infancy,—does not want to kill the goose which will lay the golden eggs at some future time. This is precisely what was done with the tea industry ; the utmost liberality—we might use the word prodigality—was shown in granting leases of waste land with conditions attached regarding the opening up of a certain proportion within a limited number of years ; and we, personally, knew one man who got three grants of 5,000 acres each, neither of which he had ever seen, and which only cost him Rs. 60 each, which charge was for preliminary survey expenses. No sooner, however, had the industry assumed a definite shape and large sums been invested in the dozens of concerns that sprang up, than down comes the Government with the Emigration Act, from which it realises a very handsome income, and the industry has since then been groaning under a load of injustice in connection with that Act and its successors, that would have crushed an industry having weaker energies or less inherent vitality. As it is, twice has the tea interest been nearly crushed. In 1864-66 the crisis was the result of overspeculation, and now it is the result of falling prices, which could be successfully combated, were Act VII. of 1873 (B.C.) repealed, and the planters relieved from a labour charge which is iniquitous and unfair, and which might be reduced by at least three rupees per man per month—this being the sum we believe the planter has to pay in excess of the fair value of the labour, owing to the exactions of that Act. The Secretary of State seems to have seen this weak spot in the recommendation regarding minerals, as he suggests that whatever change should hereafter be made, should not have retrospective effect. This is but fair. When a man enters into a contract, it is not equitable that the other party to the bargain should possess the power to alter the terms of it to his detriment. Any increase of taxation therefore, that may be made later on, should only affect prospective leases. We think the Government would have simplified matters by accepting a lordship instead of reserving the right to change the terms of leases by-and-by. By fixing a lordship of so much per ton of quartz raised, the matter of their interest in the minerals would have been settled once for all, and the question of future increase entirely avoided.

THE GOLD FIELDS OF SOUTHERN INDIA.

MR. BROUGH SMITH'S report on the Wynaad Gold Fields seems to set at rest a question of the first importance to India's future. Not only has gold been discovered over an area exceeding 500 square miles, but it is gold which can be profitably worked. Not only are the reefs "very numerous," but they exceed in average thickness those of other countries. Some of them extend for several miles; they are said to be "strong and persistent, and highly auriferous" up to 500 feet above the sea, while traces of the metal are found at a height of nearly 8,000 feet. In some places, "gold can be washed out of almost every dish of earth that is dug, and almost everywhere mining operations can be carried out at small cost. It is evident, therefore, that, sooner or later, gold-mining will be established as an important industry in Southern India." The sooner that happens, the better will it be for the Indian Government. A steady supply of gold from India would help to re-adjust the relative values of gold and silver, while it would do away with the difficulties consequent on loss by exchange.

FORESTRY.

A "TREE-FELLER."

IN these days of inventions it would be affectation to profess surprise at so comparatively simple an idea as that of a machine for hewing down trees. Messrs. Shaw, Finlayson & Co., of Calcutta, have imported a new invention for that purpose, called a "Tree-feller," which is destined for clearing forest land in Assam. Yesterday afternoon, at these gentlemen's Seed Godowns, opposite the Mayo Hospital, we witnessed, along with many other spectators, an interesting exhibition of the powers of this machine, of which we proceed to give a few details. The machine itself consists simply of a cylinder and piston (with necessary accessories) which are supported on a cast iron stand in a horizontal position about a foot off the ground. To the end of the piston rod is adjusted a detachable cross-cut saw, six or seven feet in length, and in shape like an ordinary hand saw—which of course does the actual work. The cylinder, piston, and saw in fact the whole machine turns on a pivot at the bottom of the cylinder (the movement being regulated by hand,) thus allowing of the necessary progressive motion of the saw as it cuts into the tree. The engine is supplied with steam from a portable boiler through a flexible hose of convenient length.

The first experiment conducted was with the trunk of a tree about 18 inches in diameter, which had been firmly implanted in the ground. This was felled in no time. The machine next performed on an oblong cross-grained block of wood whose dimensions were perhaps 30 × 21 inches. This was likewise severed in an incredibly short space of time—less than five minutes. Both experiments were in fact completely successful, and the results obtained highly satisfactory. The beauty of the machine lies, it seems to us, in its extreme simplicity and portability. It does not, we understand, exceed 3 cwt., and can easily be lifted by half-a-dozen coolies. The machine ought to prove valuable in some of the closely studded forests of Assam and other thickly populated wood lands.

GARDEN.

IN an article upon "Fruit," a London daily remarks:—"The mango, the mangosteen, the custard apple, and the durian, are known by repute to the people of this country; but while they might easily be frozen and brought here in admirable condition, dishes fit for the gods—no attempt is made to utilise these luscious fruits of India. Tamarind and guava jelly we occasionally get; but why not the fresh dates of the East, in place of the pressed and sticky fruit which comes to us from the borders of the Red Sea?" It certainly does seem strange that no enterprising person has attempted to establish a trade in the manner suggested.

FRUIT CULTURE.—A correspondent writes:—The great strawberry grounds near Blairgowrie, in Perthshire, which supply tons of fruit annually for the Scotch preserve makers, realize from £40 to £60 an acre, in a good year, from the beds that are at the best, and even average is as high as £25 per acre. The cherry orchards in Kent yield a still larger sum at times, but the crop is uncertain. So do the plum orchards in Worcestershire, especially in the neighbourhood of Evesham, where some 1,800 acres are devoted to fruit, and whence tons of plums in a green state are sent to the dye works of Manchester. But the most remarkable instance of high remuneration is that of Mr. Webb's fruit-ground at Calcot, near Reading. The extent is twelve acres, upon which very fine wheat was grown some few years ago; it was then planted with fruit, the produce of which amounted in one year to the astonishing sum of £4,000 or £333 per acre, cob nuts alone producing as much as £320 per acre.—*N. B. Agriculturist.*

APPLES FROM AUSTRALIA.

THE experiment of sending fresh fruits from Australia to Europe has received fresh development in the despatch and safe arrival of a consignment of apples, packed in boxes, which have been brought in perfect condition by one of the regular Australian line of steamers *viâ* the Suez Canal. The possibility of sending the most delicate fruits, such as grapes, peaches, nectarines, &c., in a perfectly fresh state, from the Antipodes to England was first demonstrated two years ago when South Australia contributed a fine selection of fruits to the Paris Exhibition, and since then small quantities of the more perishable kinds of fruit have been from time to time received in London from different parts of Australia. The facility with which apples, in particular, may be transported, since they require none of the special appliances necessary to keep the more delicate varieties of fruits in their pristine freshness, should lead to a large development of the trade. There is always a large demand for apples in England; and the southern hemisphere has this advantage over the rest of the world in supplying the English markets, that its produce would arrive at a period when the stock from last year's harvest is almost exhausted, and before the coming crop is so much as in blossom. The apple, like many other Old-World fruits, has found a congenial home in the more temperate part of Australia, just as the warmer portions of the great island continent have proved their ability to produce in perfection all the rarer fruits of the tropics and of Southern Europe. Australia, indeed, is capable of supplying us with a regular succession of luscious fruits at a time of year when the accustomed sources of supply are temporarily stopped. South Africa also might profit by the opening thus afforded of finding a market for some of the surplus yield of its orchards and vineyards.—*The Colonies and India.*

TEA.

A WRITER in the *Grocer*, a trade publication at home, has, with admirable tact, put the Indian tea subject before the home public. He writes evidently from a thorough acquaintance with his subject, and, after speaking of the system at present in vogue of mixing a sprinkling of Indian tea with a larger quantity of inferior China tea, he says—"Why should we be putting millions of pounds sterling into Chinamen's pockets, when the greater part of it might be diverted into the pockets of our own countrymen?" He says that the British public, as a rule, is willing to pay for a good article, but then it must be good if they are called on to pay highly for it. Now a mixture of, say, five parts low quality China tea with one part good Indian, can never, in our opinion, make a good tea. True, some may like it, and if there be many who prefer it, it is a very simple matter for them to purchase a pound of Chinese tea and a quarter of a pound of Indian tea, and each make up the mixture to suit their individual tastes. As matters go at present, the public taste is being utterly demoralised, and very few people at home can truly say that they know anything whatever of the flavour of Indian tea. Small quarter chests are sent home as presents, and a few shops here and there sell the fine article, but the great mass of the tea-dealing grocers sell nothing bearing the name of Indian tea, save a mixture that is utterly unworthy of the name. The correspondent referred to says—"Would it not be better to educate the public taste to the use of pure Indian teas, which are so much superior in quality and flavour to China growths, or at any rate to the rubbish now being sold in 2*s.* and 2*s.* 6*d.* mixtures?" This is exactly what ought to be done, but we need not expect the tea retailer to do this, so long as the rubbishy mixture yields him a large profit. He purchases 5lb. of China Congou at 1*s.* 3*d.* (including duty) and to this he adds 1lb. of Indian broken Pekoe-Souchong at 1*s.* 9*d.* and he has a mixture at 1*s.* 4*d.* which he sells freely at 2*s.*, or, if he wants a better tea he buys 5lb. China Souchong at 1*s.* 6*d.* and 1lb. India Pekoe at 2*s.* 6*d.*, and his mixture costs him 1*s.* 8*d.* and this he sells at 2*s.* 6*d.*; in both cases clearing 50 per cent. profit, which, if he is an energetic tradesman, he may turn over eight times a year. For this reason we cannot expect the distributing vendor to change his mode of dealing. If the tea companies of India wish to educate the British public to prefer their teas, they must undertake the task themselves, and they need not fear to lose by it, as, if properly gone about, it will from its very inception prove profitable. An effort should be made to procure a market here for our cheap teas; they cannot stand so well the incidence of freight and other charges which natur-

ally bear, relatively, much more heavily on cheap classes of goods. We have, or ought to have, a sufficiently extensive market in India to use up all our low class broken teas and dust, which, one year with another, might amount to, say, 7½ per cent. of our total produce. This would tend to keep down stocks at home, and, what is of more importance, in a very short time Indian tea would be represented at home solely by a superior article; no cheap or inferior Indian tea ever being placed on the market, the general opinion in favor of our tea could not help being raised, and our whole produce would gradually assume its true place on the market.

As a subject closely allied to this, we may advert to another phase of the tea market which has not received the attention its importance merits. We refer to the system, often recommended by us of avoiding the present method of over-classification. The 7½ per cent. of low class teas, referred to above, we would eliminate from the bulk on the garden, and the balance, without any further selection or classification, we would pack as Pekoe Souchong for the home market. We have no doubt that this would be the wisest thing to do. Let the whole bulk, less the low quality, red and coarse leaf and dust, be packed as Pekoe Souchong, and a very superior Pekoe Souchong it would make. A great saving would be effected in labour now engaged in ultra-classifying, some gardens having twelve sorts; a saving in dust and broken leaf would also be effected, as every handling of the tea must necessarily lead to waste; small breaks would be entirely got rid of, as most gardens would hand, as a rule, a hundred chests at a time to market; and a better chance would arise of gardens keeping a fairer general average of quality one year with another. That a good medium quality of tea pays best was clearly shown last year by the fact that such tea did not share in the general fall which, with a few interruptions, steadily took place throughout 1879. Messrs. Marsden and Walker, of Rood-lane, London, in their review of the Indian tea trade of 1879 say—"As compared with current rates twelve months ago, we quote:—

Common to good broken teas		...	1*d.* to 2*d.* higher.
Souchongs and Pekoe Souchongs		...	2*d.* to 3*d.* "
Medium Pekoe and broken Pekoe		...	3*d.* to 4*d.* lower.
Fine	do. do.	...	2*d.* to 3*d.* "
Finest	do. do.	...	no change.

Hence, when the higher qualities were affected by the falling market, and the lowest qualities did not advance so much the medium quality, the Pekoe Souchong, rose 2*d.* to 3*d.* per lb. This is exactly what experience would lead us to expect. A demand may exist for very low or very high qualities now and again at irregular intervals, more or less affected by the state of trade, but the demand for a good fair average quality should be, as a rule, a more constant quantity increasing steadily with the increasing knowledge of Indian teas. This good medium quality of tea is consumed by the middle classes, who are not so much affected by fluctuations in trade, and whose incomes enable them to live pretty much in the same style from one year's end to another.

The people of Australia do not apparently know what they want in the way of tea. The Melbourne *Argus*, which has recently given a considerable amount of attention to the subject, says that "it may be safely assumed that a good business would be done if the teas were selected with a knowledge of the market, and if the prices were no higher than those of the China teas." Now this, if correct, simply puts a stop to any Indian tea going to Australia, as it is well known we cannot sell as cheaply—quality for quality—as the Chinese, and principally for the reason that our system of classing is so different. A sample of China Souchong and one of Indian Souchong are as unlike as possible; the Indian being an infinitely finer quality of tea. Consequently we cannot sell anything like as cheaply as the Chinese can. The *Argus* then goes on to contradict itself in a way which leads us to the conclusion that it knows nothing of the matter at all. It first says:—"Indian teas which have hitherto come to Melbourne have, as a rule, been dearer by 5*d.* or 6*d.* per lb. than the teas ordinarily consumed here. Cheaper kinds than these will of course be sent, for it seems to be now understood, by the persons interested, that there is no demand for the high-priced sorts in Australia." Just so: we could understand this easily, if it were not directly contradicted immediately after. The most suitable size of packets is described, and then the *Argus* says:—"The packages must be properly marked and numbered, so that the qualities may be easily arranged. *Pekoe-Souchongs and Pekoes would be the best varieties to send. The common Souchongs and Congous are too rough to suit the Australian market.*" What then does the Australian market want? We are first told that it is now becoming known that cheaply priced teas are wanted, there being no demand for the high priced sorts in Australia, and then we are told that common teas are too rough to suit the Australian market, and that Pekoe-Souchongs and Pekoes would be the best varieties to send.

Force is lent to this contrast, when we reflect on the fact that the taste of the Australian consumer has hitherto been satisfied by the use of China tea, which is not by any means so good as Indian; consequently, what the *Argus* asks for, *viz.*, Indian Pekoe-Souchong and Pekoes, will be vastly superior to anything the people have ever tasted before, and very much better than the corresponding classes of China, and these they must have cheap. If this be a true description of Australian wants, we are forced to the conclusion that the colonists are a particularly unreasonable class of people. We think, however, it is more likely that the *Argus* is not sufficiently informed on the subject to be a true exponent of colonial opinion, and, after all, we shall find that, whatever class of tea the Australians may fancy, they will doubtless be willing to pay a fair price for, and, judging from the comfort and fair living which characterise the people of that vast country, we feel convinced that they will prefer a good article.

The threatened war between Russia and China may possibly lead to difficulties in the delivering of tea at the treaty ports. Should the present misunderstanding result in war, we may naturally expect that Russia will do her utmost to blockade the China ports, although whether this blockade can extend to the treaty ports is another matter, and one in which other and more interested nations will insist on having something to say. Be this as it may, certain difficulties cannot fail to be thrown in the way of trade, and it will be impossible for the China tea grower to lay his tea down in the London market at his customary low rates. This is an opportunity for the Indian grower which we trust he will be ready to embrace. Let the teas now going forward be of superior quality, and the marked superiority of Indian tea over China will be abundantly apparent to the home consumer. The break in continuity of shipments from China cannot fail to reduce stocks of that variety, and this will give the Indian variety an opportunity of being much more largely placed for consumption. It is true war may be averted (we know no foundation for the rumour in town lately that it has actually been declared), still, the uncertainty which appertains to the present unsettled state of affairs must, to a certain extent, operate against business in every department. Already the price of opium shows a tendency to rise, possibly on this very account, as it may be considered desirable to get as much as possible into the country before the war. It must not be said that the rise in price of the drug, which sold for Rs. 1,401-6-1 at the June sale, as against Rs. 1,364-7-6 at that for May, may have been caused by the pretended crusade against its use, at present being made in China, especially at Shanghai, as this we imagine would tend to lower its value. If this surmise be correct, we may expect to see a gradual increase in the value of tea at the shipping ports, which will immediately re-act in London, either in a corresponding and simultaneous rise in price, or a fall in stocks consequent on decreased imports. As we have said, in either case the Indian grower ought to be prepared to benefit by the confusion which is sure to ensue.

It is very satisfactory to note the interest Government is taking in the subject of the tea blights. We observe it is proposed to depute Mr. Wood-Mason, of the Imperial Museum, to visit the tea districts at once to study the habits of the many insects that infest the tea bushes, and that afterwards he will proceed to Europe to study the latest suggestions for their cure. Later on, Mr. Scott, Curator of the Herbarium, Royal Botanical Gardens, Calcutta, will probably be deputed to study the subject from a botanical point of view, and in the course of this latter investigation we venture to think the disease and possibly its cure may be found. We have long held the opinion that the so-called leaf diseases were not idiopathic, but really root and soil diseases, principally the former. And we have on several occasions given our reasons for holding this opinion. We have offered this opinion with all deference to that of others, who may perhaps, from lengthened experience, be better qualified to judge of the matter; at the same time we have given what seemed to us strong presumptive reasons for holding the opinion we do, and we are glad that a practical botanist is likely to be associated with Mr. Wood-Mason in his mission, as we consider the whole subject to be rather botanical than entomological. We do not allude to any peculiarity in the growth or habits of the plant, but to our modes of treating it, which, while being subversive of everything approaching nature, are, by the very necessities of the industry, imperative. Instead of helping nature in her efforts, the claims of the tea industry require that we should resist nature in almost every way. Hence we need not be surprised should disease be the result. An attack of this kind would in the natural condition be repelled by a thoroughly healthy and vigorous plant, and the fact that the disease is able to destroy the energies of the bush seems to point to a state of things where the object of attack is too weak to protect itself. The worst of this view is, that, if it is true, there can be no remedy, except one quite beyond the present condition of the industry to attempt:—a high state of cultivation, and a generous nourishing of the plants with manure,—two things out of the question in the majority of instances, on account of the present financial condition of the industry.

An Indian tea-grower has written to the London newspapers to ventilate another "serious grievance." Having been engaged for many years in the cultivation of Indian tea, of which some forty million pounds are now sent annually to England, he naturally expected on his arrival in London to be able to buy some at most of the shops where tea is sold. To his surprise he found, however, that the article was not procurable at any price in the outskirts of London, and prohibitive prices are asked for it in the city. Surely, now that Indian tea is selling in bond at an average of about 1*s.* a pound, the duty on which is 6*d.* a pound, it is surprising that a tea of which the purity is unquestionable should be so difficult to obtain. "Indian tea-grower" can only account for the fact by supposing that it is kept in the background by the grocers for the purpose of being used to cover the defects of China tea, a large quantity of which is of a very inferior character. "At one of the largest tea houses in the city," he says, "I was supplied with what was called Indian tea at 2*s.* 6*d.* a pound, but this proved to be three-fourths China, not worth half the money. Is this fair to Indian tea?"

Certain proprietors and agents of tea estates in Cachar and Assam recently addressed Government on the subject of the serious injury being done to the tea industry of India by the tea-bug and red spider. The tea-bug first appeared about 12 years ago, and all efforts of the planters to check the ravages of this pest and of the redspider have up to the present time proved futile, and nothing short of matured scientific knowledge can grapple with the difficulty. It was suggested that Dr. G. King, Superintendent of the Royal Botanical Gardens, Calcutta, as Botanist, and Mr. Wood-Mason, Superintendent of the Imperial Museum, Calcutta, as Entomologist, should be deputed to ascertain the nature of these insects, and to devise measures to protect tea crops from their ravages. Information was particularly desired as to the nature of the insect, the manner of its propagation, the time of propagation, the place of propagation, the stages of existence, the stage in which most easily destroyed, the most effectual mode of destruction and whether the modes of pruning, plucking and cultivating the tea bushes are not at fault, and what changes in this direction would be likely to have a beneficial effect.

These suggestions were accepted on all hands as deserving attention. Sir Ashley Eden fully recognizes the importance of the question, and hopes later on to be able to depute Mr. John Scott, Curator of the Herbarium, Botanical Garden, Calcutta, who has given his attention to the question of blight in connection with poppy, to thoroughly investigate the subject.

In the meantime Mr. Wood-Mason is to visit the tea districts, and observe scientifically the injuries caused to the tea plants and the nature and habits of the tea-bug and red spider. When Mr. Mason has done this, he will proceed to Europe and make himself acquainted with the most recent researches in connexion with the destruction of noxious insects, and on his return the campaign will be opened. The Government has acted with great consideration and liberality in the matter, as besides Mr. Mason's pay and expenses, it accepts the responsibility of providing the funds that may be required by the Trustees of the Museum for carrying on Mr. Mason's work during the time he is employed on the special duty referred to.

The increase in the tea industry is very marked in the Sylhet district, where no less than seventeen new gardens were registered last year. The area taken up for tea cultivation was 74,843 acres, against 54,140 in 1878; and the outturn of tea is approximately estimated from the returns, which are not, however, yet complete, at 2,161, 300lb. of tea against 1,366, 100lb. in 1878.

A correspondent at Darjeeling writes to us:—"Tea is in rather a bad way up here, as the weather is most unfavourable, and all sorts of blights have attacked the bushes. Labour, too, is very scarce, as the Teesta bridge and the tramway have taken all the strong men away from the gardens. At the Teesta bridge the coolies get Rs. 8 per mensem and the sirdars 3 pice a head. A strong willing man can earn Rs. 1 a day at the tramway, and the result is that all the labour is taken either directly or indirectly by the Government, as no tea estate could afford to pay coolies more than Rs. 6 a month."

In a resolution on the coolie immigration report of the Sylhet district for last year, Sir Stewart Bayley offers some remarks on the subject of the great length of time taken in the journey from Goalundo to the tea gardens, varying from a maximum of 36 days to a minimum of 12 days:—

"It is explained that this journey is always made by country boat, and never by steamer, the cost of the passage by the latter being found prohibitive. It is clear that the loss of so many days on the journey represents a considerable loss to the employer, and it would appear open to consideration whether the Steamer Company's Agents and the employers might not meet each other half way with the result of a considerable gain to both parties. If the cost of the passage were somewhat reduced, it might pay the employer to direct his coolies to travel by the steamer in consideration of the number of days which would be thus saved on the journey."

The direct importations into the district, during the year, of all classes of labourers for the gardens which submitted returns, were 1,619, and, if the importations to the thirteen gardens which did not submit returns be added, the number must have been much larger,—probably nearly 3,000. This includes the importations of the district of Sylhet alone, but if the importations for Cachar, to which the same remarks apply, be taken into account, the number will be very largely increased.

INSPECTION MARKS ON TEA.

The marks to denote quality, placed against Indian tea, after it has been received into the warehouse and sampled by the brokers' assistant, are as follows:—

Mark.	Quality represented.	Trade name of mark.
/	Ordinary	Straight stroke.
/.	Middling.	One a dot.
/.a	"	One a dot A.
//.	Good Middling	Two a dot.
//a	"	Two a dot A.
/—	Good	T.
/—a	"	T. A.
/‾	Fine	Gallows.
/‾a	"	Gallows A.
-/-	Extra Fine	Star.

The first three marks are only used for China, and the last one for Indian teas. "M" (musty) and "O. S." (odd smell) are added, when required, to the lower grades.

THE "BLENDING" OF INDIAN WITH CHINA TEA.

The following is from the *Home and Colonial Mail* and we commend it to the attention of blenders. The candour and descriptive ability of this retailer are to be admired. He magnanimously offers a skilfully blended Indian and China tea, a mixture of "Strong Moning" and "brisk *Indian Kaisow*," at 1*s.* 6*d.* per lb.; and his "extraordinary aptitude for commanding the market," whatever that may mean, enables him to offer the "buds and blossoms" or siftings of fine tea, which is "brisk," pungent, pure, good, and beggars the list of favourable adjectives generally in description at 1*s.* 4*d.*, or three pounds for 3*s.* 9*d.* He is considerate enough also to offer the consumer "skilfully blended spring foliage Rich Assam Pekoe and Moning Tea," at 1*s.* 8*d.*, and "Fragrant Assam Pekoe" and Finest Kaisow, of exquisite flavour and grateful bouquet, "the prime foliage of the Indies and China Souchong tea plant," at 2*s.* 4*d.* As Mr. Weller remarked of the sausages—its the seasoning as does it. So long as the public are offered mixtures of Indian and China tea, in which an expert would have to search with a microscope for the Indian kinds at prices like those quoted, it is hardly to be expected that pure Indian teas will command a high price in the market, or that the public will become acquainted with their flavour. On the other hand, more than one attempt to popularise pure Indian teas on a small scale has failed, and we hear of a recent venture in the direction which has collapsed after involving the promoter in considerable loss.

INDIAN TEA IN AUSTRALIA.

A propos of a telegram from Calcutta, announcing that the Government of this country proposed applying the sum of £1,000 towards promoting the sale of Indian teas in Australia, the *South Australian Register* of the 15th ultimo devoted an article to the prospects of the trade. The conclusions drawn by the writer, while, like others which we have lately noticed, they make too much of the apparent dearness of Indian, as compared whith China, tea, may, on the whole, be regarded as hopeful. The proposal that "afternoon teas" should be given gratis, or at a minimum charge, at the approaching Melbourne Exhibition, is spoken of as a thoroughly practical one, and likely to advance the end in view. The great drawback to the extended consumption of Indian teas, the writer says, is the price, and, with regard to the suggestion that the less costly hill varieties should be forwarded, he adds: "unless these sorts are equal, or even superior to the China teas of like price, it is perfectly useless sending them into these markets. The matter is

purely one of business. Strong as is the prejudice in some quarters against the Chinaman, no merely sentimental considerations of race will weigh with the buyer. The produce must work its way upon its merits, and the difficulty of bringing it into common use here is greatly enhanced by the fact of there being another claimant for public favour in the field."

Indian planters do not, of course, suppose that any but practical considerations will weigh with either dealers or consumers, and they wish, we imagine, nothing better than that their produce should work its way on its merits. The great point is to obtain a fair trial of its merits at the hands of the public. As to price, we believe it is entirely in favour of Indian tea. What is wanted is machinery to secure its introduction to the public at a fair price, in such a form as to suit their tastes and on a sufficiently large scale to attract general attention.

Of the plan of sending ounce packages of the tea all over the colonies free of charge, the writer does not appear to think very favourably. He says:—"This plan, although feasible enough, is of doubtful utility. The bushman is not the sort of customer that is likely to bring pressure to bear upon the merchants in respect to the kind of tea to be imported. By far the more promising plan is for the growers to establish agencies for the tea, and make it worth while of the agents to push the sale. If this course is adopted, and if upon trial it is found that India can supply as good tea as China at a cheaper price, or a better tea at the same price, there will be no difficulty in overcoming the competition which has so far proven fatal to the general introduction into Australia of the produce of Indian tea gardens."

There is no doubt that India can fulfil these conditions; but probably she must not look to the Australian merchant to aid her much in convincing the public of her ability to do so. In the first instance, at least, she will probably have to put her own shoulders to the wheel and establish her own agencies on the spot, not only for selling her teas to the local trade, but for mixing them with China teas and dealing direct with consumers.—*Englishman.*

INDIAN TEA IN ENGLAND.

OUR readers will be glad to learn that people at home are becoming less apathetic upon the subject of Indian tea. The following letter signed "Anglo-Indian" appeared in the *Grocer* and will no doubt be read by many retailers:—

"Having in view the increased supply of Indian tea we may expect to receive during the coming season, and the large stock already accumulated here (six million pounds more than at the same date last year), I would ask you to lend the valuable aid of your paper in discussing some method for increasing the consumption of Indian tea in this country. The present prices do not pay producers, and, if they continue so low, next season we must expect to see many planters ruined. This no doubt would curtail the future supply, but by what a deplorable means! Would it not be better to educate the public taste to the use of pure Indian teas, which are so much superior in quality and flavour to China growths, or at any rate to the rubbish now being sold in 2*s.* and 2*s.* 6*d.* mixtures? It is a well-known fact that when once people take to drinking pure Indian tea they never willingly give it up, though at first they may hardly appreciate its superior flavour and strength. I would propose that a society be established by those interested in the Indian tea trade, such as planters, shareholders in tea companies, merchants, brokers, those dealers who make Indian tea a speciality, and as many country firms as would be willing to lend their assistance, and that the society should have for its object, to do all in its power, by correspondence in the public papers, and by its private influence, and by any other means it might think to fit, induce the public to use, and the grocer and packet companies to supply, a good drinkable mixture of pure Indian tea. I feel sure from personal experience how many would appreciate being able to buy Indian tea, fit to drink, at their grocers instead of having, as many who know about it now do, to procure it in larger quantities than they require, through some friend in the trade. I am certain you must have many influential readers who would carry this idea through with success, if only they have the public spirit to undertake the task. Why should we be putting millions of pounds sterling into Chinamen's pockets when the greater part of it might be diverted into the pockets of our own countrymen? There is plenty of room in India and Ceylon to enlarge the supply, were once a greater demand for Indian teas to spring up. I trust I have not written this in vain, but that before many years have elapsed we shall see the 160 million pounds we consume each year of China tea supplied by our own fellow-subjects in India, and not by the inhabitants of the Celestial Empire."

THE CHINA MARKETS.

THE London Commercial Correspondent of the *Bombay Gazette* writes (May 7):—A good deal of interest is felt in Mincing-lane on the question of the relations between Russia and China. I will not say that holders of tea and even sugar hope for war, but they undoubtedly contemplate the chance of it with much equanimity. For some three weeks past the tea market has been wretchedly depressed, and over 100,000 packages have been sold at public sale "without reserve," mainly on account of speculators, whose purchases, made last autumn, had resulted in an average loss of 20 or 30 per cent., and in many cases much more. It is now assumed, however, that should war break out before the new Congou is shipped in any quantity, a renewed speculative excitement may occur. During a former China war, common Congou, as it happens, was quoted even lower than it is at present, but then it is also pointed out that by July next we may probably have only two months' consumption of tea in the country, a scarcity perhaps unprecedented. There is certainly a fine opening here for speculative movements. At the same time the calculation omits a good deal, as, for instance, the doubt whether the other Powers would allow Russia to blockade the Treaty ports, and also the tolerable certainty that, in the worst event, considerable shipments might be made at Hong-Kong. The losses just referred to in tea might, I may mention, be extended to many other articles. I know several cases in which foolish speculations prolonged beyond the time of top prices early this year have led to the ruin of persons in business who have had to appeal to their friends for help, to avoid the discredit of a public bankruptcy. The commodities thus dealt in and the cause of the heaviest losses—after tea—have been sugar, silk, and hemp. In the last named case some very wild speculation went on. It seemed at one time as if the price of hemp would go much higher, and one or two operators who had bought cheap, and might then have cleared out at a good profit, held on, and not only so but went in deeper, buying at the top price of the market. It is needless to dilate on the sequel. I know one man in business, still young, who brought home £25,000 from China half-a-dozen years ago, and has since done a safe quiet commission business, but who in an evil hour for himself "went into" silk and lost £8,000. Then, by way of recovering his loss, he had another little "spec" in silk, from which, after various fluctuations, he emerged with a small profit. This encouraged him and he made a fresh essay in the market, going deeply into hemp and silk. Both rose, and he could have come out with a very handsome profit, but instead of doing so he bought more of both commodities. Immediately afterwards the reaction came and insolvency quickly followed. He held on as long as he could, then was obliged to close, and is now cleared out, penniless, and in debt to his relatives. This is but one case in point, but it is an illustrative specimen of scores, involved by the decline in many other markets as well as silk and hemp.

TEA-TASTERS IN NEW YORK.

THERE are, says Dr. Dana, probably more than a hundred firms engaged in tea-tasting in this city. In all of their offices there are large tables with round revolving tops. A circle of teacups is placed along the edge of these. The tea-taster sits down before this display of crockery and tastes one cup after another, moving the table top round. In the centre of the table is a pair of scales with a silver halfdime in one of the balances. One or two large kettles are kept constantly, with boiling water in them. When a sample of tea is to be tasted, as much is weighed out as will balance the halfdime. This is put in a teacup and the boiling water poured on. The tea-taster then stirs up the leaves, lifts them on his spoon, and inhales the aroma. At the same time he generally takes a sip of the infusion, holds it in his mouth for a short time, and then spits it out. Enormous brass cuspadores, holding two or three gallons, receive the teas thus tasted and the contents of the cups that have been examined. On some occasions, when a large amount of tea of a certain kind is to be bought, many samples of this are brought in from different houses. The buyers and sellers sit around the revolving table with the samples made into infusions in the cups before them. These are tasted all around, the "body," "fineness," "toastiness," &c., are learnedly discussed, and the poorer specimens discarded. Then those that are left are tasted again and the number further reduced. So it goes on until the article which unites the desired quality and price is obtained.

The skill displayed at those "drawings" is quite remarkable. A tea-taster will detect not only the quality of tea as regards age, strength, flavor, fineness, &c., but he can tell in which of the numerous districts in China the tea was grown. The facts regarding the different samples are sometimes put on the bottom of the cups, where they cannot be seen. The cups are then mixed up, and the infusions tasted again and sorted out simply by their flavors.

A great deal of tea may be tasted before these tea-drawings are finished. It is hard to tell the amount that a tea-taster takes during the day, for it varies a great deal with the activity of business. Few of the gentlemen whom I asked could give any idea. Sometimes, however as many as four or five hundred cups are tasted in the day. It is qu[illegible] the custom to have to be tasting tea steadily for most of the day, or for hours at a time. Probably an average of 200 cups a day throughout the year is a low estimate. The poorer kinds of tea are often not sipped at all, but the sense of smell is depended on. Of the better qualities of tea, some is swallowed, and some spit out. Indeed, whenever the tea is taken into the mouth a little of it is swallowed. The tea gets into the system, therefore, in three ways, by inhalation, by absorption, through the oral mucous membrane and by the stomach. More tea is simply taken into the mouth without swallowing than is inhaled alone, but all the tea is inhaled, even it is tasted also. It is only a small proportion, amounting to not more than two or three cups a day, that is swallowed. A silver five-cent. piece weighs 1·18 grm. (gr. XVIII.) Estimating that an average of 200 cups of tea are tasted per day, about one-half of a pound would represent the whole amount used.

Japan tea has of late years become by far the most popular variety, and more of it is imported than of all other kinds together. Green tea, on the other hand, is much less extensively used than formerly.—*Ceylon Times.*

TEA PROSPECTS.

Mr. Albert Smallwood has sent the following letter to the *Darjeeling News* :—

Sir,—The result of a short visit I paid lately to the Darjeeling district, satisfied me that planters generally are not only in a very despondent state of mind, owing to the low prices their teas are fetching, but are inclined to be reckless; assuming that it matters little what class of tea they turn out, as there is only one price for the best and the worst. In fact, attributing the present serious depression to every cause but the right one.

Statistics, as a rule, are a very dreary subject, but in the case of tea, those of the last three years so fully account for the present state of the tea market, here and at home, that I will inflict them on your readers.

In 1878, the export from India was, 33½ millions of lb., the consumption at home 36¾; but in 1878 the export rose to 38¼ millions, while the consumption at home fell to 35¼. In other words, the supply exceeded the demand,—the result of bad trade and a wretched harvest at home. Now, the report for 1880 promises to be 45 millions of pounds, and the consumption to 30th April is only 12¾—*i.e.*, for one-third of the year. The effect of these low prices will of course be to stimulate the consumption of Indian tea, and until the supply and demand again approximate, planters must be contented with low prices.

The Tea industry is now suffering from the heavy extensions of 1873 and 1874.

The declining prices of the last three years have effectually checked further extensions of any moment, and I consider that after this year the quantity of Indian tea for export, is likely to fall off rather than increase.

Of the three large tea districts, Darjeeling is certainly at present in the best position. There is no reason why a full-bearing garden in Darjeeling should not sell its tea in Calcutta, all expenses paid, for 7 and 7½ annas per lb. It has been done for less,—but Cachar, so far, has failed to make and sell its tea under 9 annas ; and in most instances, last year, it was 10 annas and over. This means a collapse in the case of most of the old Teelah gardens.

Assam is as bad as Cachar, if not worse,—the coolie expenses are so enormous; and this year, owing to a good crop in the recruiting districts, the coolies are so hard to procure at any figure, that many gardens there are abandoning considerable portions of low class plant.

There is a fallacy, almost amounting to conceit, which pervades the minds of tea planters in India, *viz.* that Indian tea is superior to China. I can only say I have samples before me of Chinese tea, selling at home at 10*d.* per lb., which could put to shame some of the teas sent down from Darjeeling, as the result of their first flush this year, which planters consider sacrificed at 9 annas. Darjeeling tea, without that delicate aroma which should distinguish it from all other teas, is weak and tasteless, and China tea always has the advantage as far as make and appearance are concerned.

The demand in London at present is chiefly for Darjeeling teas, but then they must have something to recommend them, either flavor or quality, and those now coming to market have neither. Planters constantly tasting their own teas, begin to believe in their own manufactures, and only get put out of conceit when they find, on competing with others, how indifferent they are.

There is no sufficient interchange of ideas or samples in the Darjeeling district ; men fence themselves in, as if all their neighbours were robbers, and every effort to bring about a change in this respect is looked upon as interference.

A few words of hope in conclusion. The imports of China tea into London fell off in 1879 for the first time for many years, and the present low prices at home may have the same effect in 1880, and thus an improvement in the prices of Indian teas may take place in the autumn, when it will be too late for China to make up any deficiency there may be ; but if the rise comes earlier, the "Heathen Chinee" will flood the London market.

China in 1879 sent to England, Australia, and America 280 million pounds of tea. Take Russia at 80 million pounds, and the home consumption in China being estimated, at the least, at 210 millions of pounds, planters can see what a drop in the ocean Indian tea really is, and how long it will be before it is universally applied to any other use than mixing, and how necessary it is that its quality should be maintained.

COFFEE.

Coffee is more largely grown in the Madras Presidency than in any other part of India. We take the following from an official paper issued in Calcutta :—"The exports of this article, principally from the Madras Presidency, show a tendency to a steady increase, the values exported during the last three official years having been 132¾, 154½, and 162¾ lakhs of rupees. Usually an increasing export trade is a sign of progress. In this case we fear it must not be taken in that light, as the consumption of this article being almost stationary, an increasing production simply means lower prices for the grower. The only increase observable in the use of coffee is that due to the normal increase of population, the consumption per head remaining stationary, while the increase in exports, as above noted, amounts to 11 per cent. per annum."

Liberian Coffee.—We learn from the report of the Madras Agri-Horticultural Society that the introduction of Liberian Coffee into Madras and its nighbourhood may, the Committee think, be declared a failure. The plants in the gardens have most of them perished in spite of every care, and those that survive still maintain the character of shrubs rather than of trees, though now upwards of three years from the seed having been received in the gardens from Kew in July, 1877. The healthiest plants the society now possesses are from cuttings made from what the planters call expressively "Gormandising suckers." The plants in the ground, amongst the shrubs in the ornamental garden are still in better health than the survivors of those that were planted in the open in the experimental garden, but they grow very slowly, and though they have two or three times flowered, any fruit which has set hitherto has burned black and fallen.

CLOSE PLANTING OF COFFEE.

On this subject a practical planter writes :—

"The place——mentions in Maskeliya was planted an unusual distance, but 6 × 4½ cannot be called close, ; 5 × 5½ gives more trees to the acre.* That about close planting to prevent sourness in the soil, I thought at the time to be great nonsense : send the writer a copy of 'Talks about Manures.' Land well drained and tilled without any crop will never get sour. But some land can be sweetened by simple tillage alone. Take the case of bog or marshy land that has often to be allowed to lie idle for a year or more after being reclaimed before any crop will grow in it. And the absence of feeding roots in coffee now-a-days is a mere idea. They are not so often seen as in the days of mamoty weeding, &c., but let a drain burst, as some of mine did the other day, and carry away one or two below it, and if it is ordinary coffee, there will be no end of roots exposed. I believe in close planting all the same, but for a very different reason. Clearings haven't the same chance in the way of shelter since the country was bared of forest, so that in close planting the one helps to shelter the other. A thickly sown nursery comes up faster and grows more rapidly than where the seed is thinly sown. 'Fruit *vs.* Leaves.'—The *Observer* gave it not long ago on the authority of Mr. Hughes that our soil was being more rapidly exhausted from the loss of leaves through leaf disease than if our coffee were giving good crops of berries."

That was not the question lately put before us ; but it was whether say 4 cwts. of coffee berries per acre or 4 cwts. of tea leaves, exhausted the soil most. Of course, a great deal depends on circumstances, and, weight for weight, in many cases the effect might be nearly the same, but nevertheless, we think there can be little doubt that fruit berries is the more exhausting crop of the two. Leaf *disease* sweeping away flush after flush of leaves for months together, just when the tree wants nourishment, may well be said to do more harm to tree and soil than a big crop grown in the ordinary way.

CINCHONA.

EXPERIMENTS IN CINCHONA ALKALOIDS.

We have been favored by Government with the first report of the Surgeon-General, Indian Medical Department, on the experimental trial of the following cinchona alkaloids in the treatment of malarious fevers, *viz.*, sulphate of cinchonidine, sulphate of cinchonine, and Sikkim cinchona febrifuge. The report embraces the period from the beginning of the inquiry till the 31st December 1879. The cases in which *Sulphate of cinchonidine* was used were as follows :—

Type of Fever.	No. treated.
Quotidian	768
Tertian	47
Quartan	143
Remittent	12
Total treated ...	970

Of these, the drug cured 849 and failed in 121 cases. The average dose given was 6·24 grains, and the average entire quantity administered in each case was 87·93 grains. The average period each case was under treatment was 5·86 days. In some instances the drug induced nausea or vomiting, effects which sometimes follow the use of even quinine. The cases treated by *sulphate of cinchonine* were as follows :—

Type of Fever.	No. of Cases.
Quotidian	776
Tertian	80
Quartan	47
Remittent	14
Total treated ...	917

Of these, 805 were cured, 109 were not cured, and 3 died. The average dose given was 9·52, and the average total quantity of the drug administered in each case was 109·57 grains. In some instances nausea, vomiting, purg-

* No ; 6 × 4½ gives 1,613 tree, and 5 × 5½ equals 1,590 trees ; much about the same, but decidedly more than the ordinary number.—Ed., *C. O.*

ing, or headache ensued. The average time required to check the fever was 6·55 days. The cases treated by *Sikhim febrifuge* were as follows :—

Type of Fever.	No. of Cases.
Quotidian	... 2,235
Tertian	... 389
Quartan...	... 572
Remittent	... 2
Total treated	... 3,198

Of the treated, 2,915 were cured, while 270 were not cured, and 13 died. The average dose of the febrifuge given was 7·66 grains, and the average total quantity administered in each case 80·78 grains. The administration of a dose was often followed by giddiness and the signs of gastric disturbance, such as nausea, vomiting, or purging, were much more common and more severe than in the case of either cinchonidine or cinchonine. On an average it took 5·46 days to check an attack of fever with this remedy. The results of the trials are given and contrasted in the following table, but the comparison, Dr. Smith remarks, is not quite a fair one, as there were so many more cases of fever treated by Sikhim febrifuge than by either of the two other remedies :—

Cinchona preparations.	Average dose given.	Average total quantity of drug given in each case.	Average number of days each case was under treatment.	Total number of cases treated.	Cured.	Not cured.	Died.
	GRS.	GRS.					
Sulphate of cinchonidine	6·22	87·93	5·86½	970	849	121	...
Do. of cinchonine ...	9·52	109·57	6·55	917	805	109	3
Sikhim febrifuge ...	7·66	80·78	5·46	3,198	2,915	270	13

It appears that a less quantity of the Sikhim febrifuge was required than of either cinchonidine or cinchonine to cure an attack of fever. The actual average quantity used of each febrifuge was as follows :—

	Grains.
Sikhim febrifuge	80·78
Sulphate of cinchonidine	87·93
Do. of cinchonine	109·57

From these figures it appears that the Sikhim drug is the most active of the three, sulphate of cinchonidine the next active, and sulphate of cinchonine the least active as a febrifuge. The Sikhim febrifuge had also the advantage as regards the time required to effect the cure of paroxysm of fever—a point of great importance as regards the soldier and also as regards some of the labouring classes. The following are the figures :—

	Days.
Sikkim febrifuge	5·46
Sulphate cinchonidine	5·86
Do. cinchonine	6·55

In this respect, also, therefore, the three preparations hold the same relative positions.

The relative curative merits of the three drugs, as shown by the figures given above, may be illustrated as follows :—

Preparations.	Rate per cent. of Cured to treated.	Not Cured to treated.	Deaths to treated.
Sikhim febrifuge ...	91·15	8·44	·40
Sulphate of cinchonine ...	87 78	11·88	·32
Sulphate of cinchonidine ...	87·52	12 47	...

This places the Sikhim febrifuge first on the list as a febrifuge, cinchonine next, and cinchonidine lowest. These results, says the Surgeon-General, are somewhat, unexpected, and must not be regarded as final. Further experiments are in progress, and in due course the available data will be sufficiently numerous to indicate authoritatively the respective merits of the three preparations. The unpleasant effects caused by the Sikhim preparation were marked, and still form the chief obstacle to its more extended use.—*Madras Times.*

CINCHONAS IN GENERAL AND C. CALISAYA IN PARTICULAR.

I.
